Received 3 May 2006; revised 6 June 2006; accepted 31 August 2006; published 3 January 2007.

[1] Firn air and ice have been sampled and analyzed for trace gases (CO₂, N₂O, CH₄, and CO) and isotopes (¹⁴C, ¹³C, and ¹⁸O of CO₂; ³H of ice) at 3 m intervals from the surface to the depth of closure at 60 m on the Devon Island Ice Cap, a low-elevation permanent glacier in the Canadian Arctic Islands, to investigate firn diffusion and the effects of summer melting. The ¹⁴CO₂ profile from the permeable firn includes the 1963 thermonuclear peak at a depth of 53.9 ± 1.5 m. The twofold increase and rapid decay that characterize the recent atmospheric history for ¹⁴CO₂ provide a robust atmospheric scenario that is used with a firn air diffusion model to inversely construct the firn diffusivity profile. The results show a permeable but essentially nondiffusive zone from 50 to 60 m depth. A firn-ice age profile was produced from density measurements, and accumulation rates were calibrated with the depth of the 1963 thermonuclear ³H peak. The average ages for CO₂ in the sampled firn air profile were determined by a new method based on the rate of ¹⁸O exchange between CO₂ and the ice matrix. Calibrated with the 1963 peak for thermonuclear ¹⁴CO₂, a 21.2-year reaction half-time is calculated for exchange taking place at the firn temperature of -22.8°C on Devon. This gives an average age of 54.9 (+6.0/-12.0) years for firn air at 60 m depth in 140-year-old ice. Thus CO₂ has a mean age 85 years younger than associated ice at the point of occlusion. The measured δ¹⁸O_{CO₂ in firn air provides no indication of alteration by summer melting, which is attributed to a high degree of convective and diffusive flushing of the upper firn as shown by diffusion modeling. This suggests that ice sheets with summer melt layers can reliably preserve atmospheric trace gas signals.}

Barnola (2007), CO₂ isotopes as tracers of firn air diffusion and age in an Arctic ice cap with summer melting, Devon Island, Canada, *J. Geophys. Res.*, 112, D01301, doi:10.1029/2006JD007471.

1. Introduction

[2] The trace gas record in air bubbles of ice cores from high-latitude glaciers provides a baseline for calibrating twentieth century increases in anthropogenic gases, although rates of firn accumulation and densification rarely generate an average age of trapped air younger than about 40 years [Schwander and Stauffer, 1984]. The atmospheric record found in the firn air column of selected ice sheets can

be used to bridge ice core records with direct measurements begun in 1958 [Keeling and Whorf, 1998]. Trace gases in the firn air column also provide insights into the densification and air trapping process. Firn air diffusion partly controls the mean age of the firn gases being trapped. However, the rates of firn accumulation and temperature of the glacier greatly affect firn air diffusion, the depth of entrapment and hence the time period preserved by the firn air profile. The effective firn diffusivity profile is then the principal feature controlling firn air diffusion and so is important for reconstructions of the age profile within polar firn [Fabre et al., 2000].

[3] Firn diffusion in dry accumulation ice sheets is well documented [Schwander and Stauffer, 1984; Stauffer et al., 1985; Schwander et al., 1988, 1993; Schwander, 1989, 1996; Fabre et al., 2000]. Typically, three zones within the firn column are identified: (1) the convective zone, (2) the diffusive zone, and (3) the nondiffusive zone of occlusion [Schwander, 1996]. The shallowest is the convective zone, which occurs in the upper ~10–15 m of firn. In this uppermost zone, wind pumping, barometric and temperature variations in the open atmosphere act to exchange firn

air with the overlying atmosphere on short timescales and to attenuate any annual variations. In the underlying diffusive zone, mixing of trace gases is due to molecular diffusion with overprints of gravitational settling. Only when abrupt surface temperature change occurs does the diffusive zone experience temperature-driven fractionation of gas composition (thermal diffusion [Severinghaus *et al.*, 1998, 2001]). Between the diffusive zone and the depth of bubble close off (where open porosity is occluded) exists a narrow nondiffusive zone where open porosity exists, but highly restricted permeability precludes vertical diffusion. Typically, this 10–20 m zone starts around 50 to 100 m depth.

[4] Firn air diffusion and occlusion has been mostly studied for cold glaciers with dry firn to preclude the complications that seasonal melting might have on CO₂ mixing ratios and isotopes in preserved firn air. Summer melting is a common phenomenon for low-altitude or low-latitude glaciers. Surface temperatures over a several week period can rise above 0°C, causing snow from the previous season to melt and infiltrate the snow pack. Infiltrating melt water then percolates through the snow pack and refreezes near the base of the winter's accumulation as horizontal lenses and irregularly shaped infiltration channels [Koerner, 1977] according to the stratigraphy of the ice (Figure 1). The result is an increase in the anisotropy of firn air permeability, and a reduction in vertical diffusivity [Fabre *et al.*, 2000]. Such firn may preserve a longer firn air CO₂ record with a better time resolution than firn without summer melting. By contrast, the melting that occurs threatens to contaminate the CO₂ record, as well as the ¹³C and ¹⁸O record of the CO₂, through dissolution and chemical reactions during the melt-refreeze cycle [e.g., Neftel *et al.*, 1985]. A study conducted on a high-altitude French glacier did encounter seasonal melting, but the very high wind speed at this location generated unusually high effective diffusivities with depth [Sturges *et al.*, 1996], and erased any effect of melt layers on trace gases. Trudinger *et al.* [1997] noted a significant effect on firn air mixing by a melt layer on Law Dome, Antarctic. Sturrock *et al.* [2002] found that refrozen ice layers complicated firn air diffusion model tuning.

[5] Unlike most Antarctic sites, the low-altitude ice caps of the Canadian Arctic Islands are affected to varying degrees by summer melting, and provide the opportunity to study such effects on firn air diffusion. Accordingly, a firn-air sampling program on the Devon Ice Cap was undertaken in April 1998, in collaboration with the Geological Survey of Canada and the FIRETRACC/100 European research consortium (Firn record of trace gases relevant to atmospheric chemical change over 100 years [Sturges *et al.*, 2001]). In this work, we examine CO₂ and CH₄ in firn air from Devon to determine whether ice caps with summer melting can provide a useful record of atmospheric trace gases. In particular, the distribution of ¹⁴CO₂ is examined as a discrete trace gas with similar diffusive behavior to CO₂ but with a very different atmospheric input history. The 1963 ¹⁴CO₂ bomb peak provides a robust time horizon that can be observed in firn air [Smith *et al.*, 2000] and ice [Levchenko *et al.*, 1996, 1997]. Decoupling of these two trace gases in firn diffusion modeling provides a constraint on the age of firn air CO₂. The exercise also resolves the vertical diffusivity

profile and depth of occlusion in firn on a glacier with seasonal melting.

1.1. Devon Island Ice Cap

[6] Firn air samples and core were collected from the summit of Devon Island Ice Cap, Nunavut, Canada (75°20'N, 82°08'W, 1929 m asl). The Devon Island Ice Cap is a subpolar cap within the Canadian Arctic Islands spanning 15,570 km² and occupies the eastern portion of Devon Island (31% of the island's area). Snow accumulation on the ice sheet varies from greater than 40 g cm⁻² y⁻¹ on the eastern slopes to less than 25 g cm⁻² y⁻¹ on the northwestern side of the ice cap [Koerner, 1979]. Koerner and Taniguchi [1976] calculated the accumulation rate to be approximately 22 g cm⁻² y⁻¹ at a nearby site to the present one, on the basis of the depth at which the 1963 tritium peak from thermonuclear bomb-testing is preserved in the firn.

[7] The present atmospheric circulation of the Canadian Arctic Islands is dominated by a westerly circumpolar vortex in the middle to upper troposphere located over the Arctic Ocean [Maxwell, 1980]. Regionally, this results in a cold southwesterly air flow in winter. Upon retreat of the Arctic air mass in summer, a more zonal westerly flow predominates, with significant heat and moisture exchange from Baffin Bay to the east. An automatic weather station, located approximately 1 km east of the summit, has been recording weather data since the spring of 1997 and indicates the measured mean annual air temperature to be -23°C (Figure 2). Over the majority of the year, the temperature is well below freezing, reaching lows of -40°C in the winter months. However, up to two weeks in June and early July can experience temperatures above freezing, causing melting of the annual surface layer.

1.2. Field and Laboratory Methods

[8] Firn air was sampled in April of 1998 from 18 intervals between the surface and the firn-ice transition below 60 m depth, on the basis of the extraction method of Schwander [1989]. Firn air sampling took place during the initial stage of a drilling program to extract an ice core from the surface to the base of the ice cap. An electromechanical drill developed by the Geological Survey of Canada was used. Firn was cored to the desired firn air sampling depth, upon which the core and the drill were removed from the borehole. A 3 m long inflatable rubber packer with a 5 cm sampling port at the base was then lowered to the bottom of the borehole. The packer was tethered with a braided steel wire cable and an inert, three-tube Dekabon 1/4 inch sampling hose connected to a manifold on the surface that interfaced a metal bellows firn air pump, pressure gauges, and LiCOR infrared CO₂ analyzer. The packer was inflated through one of the three tubes with firn air from the packed-off zone pumped to surface through a sampling tube linked to the bottom sampling zone and back to the packer. Air was also continuously pumped to waste through the third tube connected to the zone immediately below the rubber packer, at a flow rate higher than the air sampled from the lower zone. The purpose of this so-called "Bender baffle" was to remove any possible contamination of firn air from rubber degassing. The CO₂ content of the air pumped through the sampling tube was monitored in order to assess when firn air uncontaminated

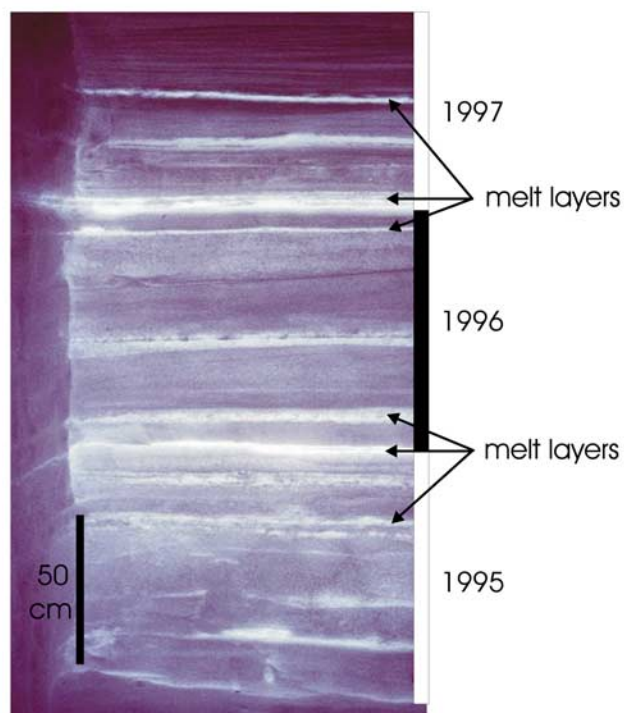

Figure 1. Backlit section of firn stratigraphy showing annual accumulation with melt layers (shown as clear laminations), Devon Island Ice Cap.

from ambient air in the borehole could be sampled. Once the LiCOR stabilized at a minimum CO₂ value (with variations typically in the range of 0.1 to 0.5 ppm), three pre-evacuated 2 L glass flasks were filled to two bars above ambient pressure from each sampling depth for our measurements. All air samples were dried by pumping in-line through an anhydrous magnesium perchlorate column. A surface air sample was also taken according to the same protocol by placing the bladder at the surface, approximately 100 m upwind (southwest) of the drilling site.

[9] Trace gas mixing ratios for CO₂, N₂O, CH₄, and CO were analyzed by gas chromatography at the Meteorological Service of Canada (MSC) laboratory in Downsview, Ontario, Canada (Figure 3). The CO₂, N₂O and CO measurements are directly traceable to the international CO₂, N₂O and CO mole fraction scales maintained by the WMO Central Calibration Laboratories (CCL) at the NOAA/CMDL facilities in Boulder, Colorado. The MSC maintains a set of National Standards that are regularly calibrated by NOAA/CMDL approximately every 2 years. The CH₄ reference scale is propagated from a Standard Reference Material cylinder purchased from the National Institute for Standards and Technology (NBS SRM-1658a, 913 ± 10 ppb). The CH₄ scale employed for this analysis is a factor of 1.0151 higher (approximately 25 ppb at ambient level) than those determined at NOAA/CMDL. The ¹³C/¹²C and ¹⁸O/¹⁶O composition of CO₂ were also measured at the MSC laboratory by isotope ratio mass spectrometry (MAT 252 dual-inlet mode), and have been corrected for the presence of N₂O (Table 1, Figure 5). The δ¹³C and δ¹⁸O values of the reference gas are -11.91 and -10.38, respectively, on the primary scale of VPDB-CO₂. Details of the traceability for isotope measurements at MSC can be found in the work of Huang *et al.* [2003]. Measurement precision was ±0.05‰ for δ¹³C but was much larger (±1‰) for δ¹⁸O

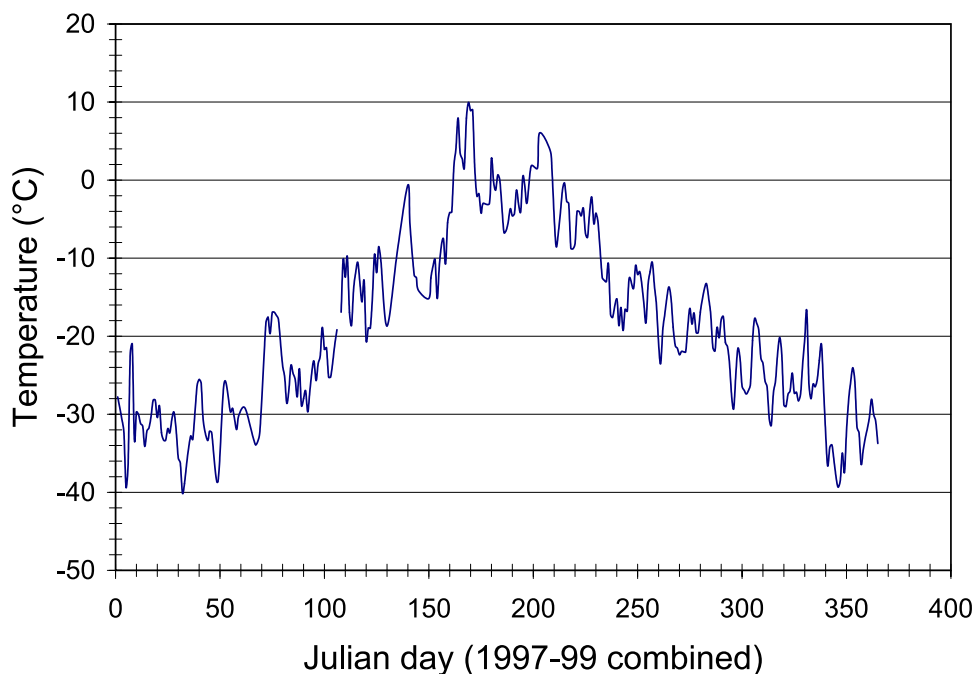

Figure 2. Seasonal temperature variation for the summit of the Devon Island Ice Cap.

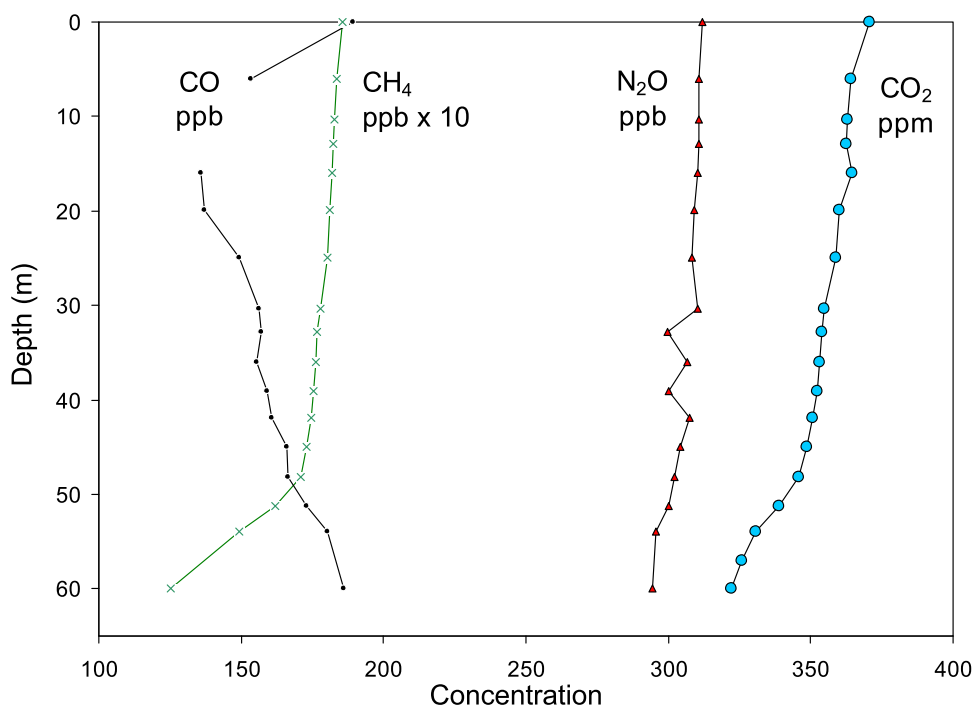

Figure 3. Trace gas concentrations in firn air sampled in the Devon 98-1 drill hole on the Devon Island Ice Cap.

in some samples owing to isobaric interference by trace amounts of ethanol believed to have originated from the vacuum line during sample preparation. Sample gas in the MAT 252 bellows was analyzed repeatedly (2x or more) to ensure reproducibility. Samples containing ethanol contamination (15.95, 30.33 and 32.85 m depth; Table 1) exhibited $\delta^{18}\text{O}$ values that were shifted significantly after approximately 10 minutes. The measured $\delta^{13}\text{C}$ values were unaffected. Previous tests of gas mixtures containing CO₂ of known isotope composition and containing trace amounts of ethanol suggest the initial $\delta^{18}\text{O}$ measurements were closest to the true value for CO₂, so initial rather than average $\delta^{18}\text{O}$ values for repeated runs are reported here.

[10] As can be seen in Figure 3, CO₂, N₂O, and CH₄ firn air profiles show a decreasing trend with depth, with a more pronounced slope below ~48 m. These features are similar to those observed from previous firn air sampling operations in polar glaciers and result from the increased atmospheric mixing ratios with time. On the contrary, CO decreases by about 50 ppb between the surface and 15 m, followed by a strong increase to 185 ppb at the close-off region. The first feature results from the strong seasonality of CO mixing ratios, which for Alert varied from 68.5 ppm in August 1997 to 182.8 ppm in February 1998 [Steele *et al.*, 2003], and was on its decreasing trend at the time of atmospheric sampling at Devon Island. The increase with depth (age), however, is not consistent with CO temporal trends over the last decades, which suggest an increase during industrial time until the late 1980s [Zander *et al.*, 1989] and a decrease of over 20 ppb since then [Steele *et al.*, 2003]. Ice core measurements performed on Greenland ice [Haan *et al.*, 1996] revealed a large decrease of atmospheric CO in the Arctic going back to pre-industrial levels of less than 100 ppb. In situ production by cosmic radiation of organic

matter [Colussi and Hoffmann, 2003] can be excluded given the high rate of diffusive exchange with the open atmosphere. On the other hand, measurements of some halocarbons in Devon firn air sampled in our program also indicated larger mixing ratios in the close-off area compared with the surface. This suggests a common mechanism or atmospheric scenario in this region is responsible for artifacts in both CO and some organo-halogens [Sturges *et al.*, 2001].

[11] The CO₂ in 18 firn air samples was extracted from the flask samples at the University of Ottawa and submitted in glass break-seal tubes for ¹⁴C AMS analysis at Isotrace Laboratories, Toronto, Ontario. Sample volumes for CO₂ averaged ~80 μmol at STP. Calculations of in situ ¹⁴C produced in firn ice, as described by Lal *et al.* [1997], show this to be 60 atoms per gram of ice. For firn with density of 0.5, this amounts to 0.45% of the minimum concentration for ¹⁴C in the firn air (30 atoms in situ ¹⁴C per 6720 atoms atmospheric ¹⁴C). Further, in situ ¹⁴C, which occurs as both ¹⁴CO and ¹⁴CO₂, is trapped within the firn ice matrix and is not necessarily sampled by firn-air pumping. Much of that which may diffuse to open firn air will be lost through exchange with the open atmosphere. This is consistent with the work of Smith *et al.* [2000], who found no evidence for additional contributions to ¹⁴CO₂ in the bomb peak measured in firn air from Law Dome.

[12] The age structure and rate of accumulation of the firn was established from tritium measurements. Forty-one firn samples, at approximately 50 cm intervals from the surface to 23 m ice depth, were analyzed for specific activity of tritium using a Wallac Quantulus 1220 liquid scintillation counter in the Low-Background Building counting facilities at AECL-Chalk River Laboratories. Sample aliquots of 10 mL were mixed with 10 mL of Packard Picofluor LLT

scintillator and beta-counted for 24 hours resulting in an overall precision of ±7 TU (Figure 4).

2. Results and Discussion

2.1. Age Structure of Firn Ice

[13] The distinct 1963 peak in the tritium profile appears at 16.6 m in firn ice whereas the ¹⁴CO₂ peak in firn air has a much wider distribution centered at 53.9 m (Figure 4). The depth of the tritium peak is used to calculate the average rate of accumulation over the last 35 years to be 30 g cm⁻² yr⁻¹ of ice, which is within the range found for sites on the northwestern and eastern ice cap [Koerner, 1979]. This rate

of accumulation, corrected with firn density measurements (presented in Figure 9), is extrapolated to the lowest sampling point at 60 m, yielding an age for firn ice at this depth of 140 years before 1998, and 1858 as the year of accumulation (Figure 7). Fisher *et al.* [1996] show that the rates of accumulation on Devon and other Canadian Arctic Island ice caps have had little variability over the past few hundred years.

2.2. Age Structure of the Firn Air Column

[14] The age of firn air CO₂ has been reconstructed using a new method based on the exchange of ¹⁸O between CO₂ and the ice matrix, calibrated with the firn air sample that

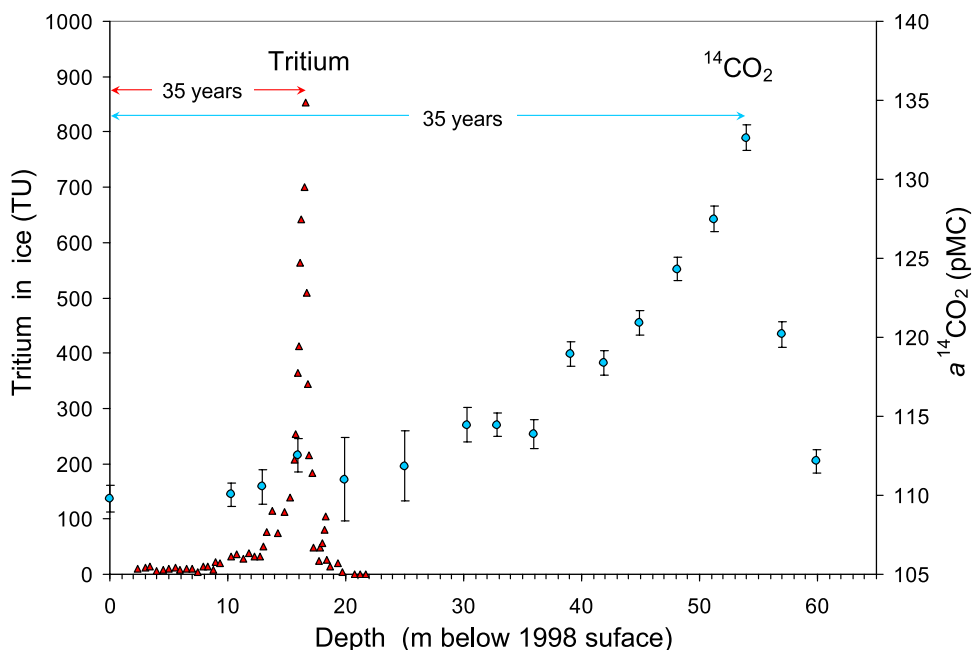

Figure 4. Tritium profile in the Devon 98-1 firn ice, together with atmospheric ¹⁴CO₂ in firn air, normalized to CO₂. Peaks in both profiles represent the 1963 thermonuclear bomb-test peak (35 years old in 1998).

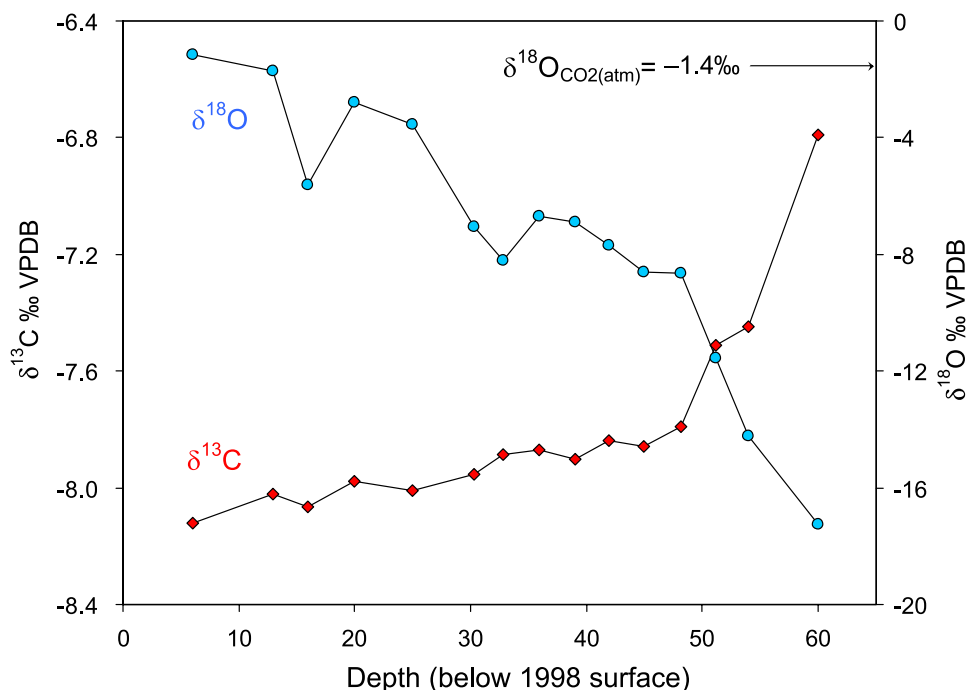

Figure 5. Depth profiles for the stable isotopic content of CO₂ (uncorrected for gravitational settling and diffusion) in Devon 98-1 firn air. Anomalous values for $\delta^{18}\text{O}$ at 15.95, 30.33, and 32.85 m are due to ethanol contamination during analysis.

includes the 1963 $^{14}\text{C}_{\text{CO}_2}$ thermonuclear bomb peak. Figure 5 shows the variation of the stable isotope contents (^{13}C and ^{18}O) of CO₂ in the firn air column. The ^{13}C profile shows a steady enrichment with depth from a modern value of -8.12‰ , to a value of -6.79‰ at the transition zone. Corrected for gravitational settling under conditions of diffusive equilibrium [Trudinger *et al.*, 1997; Francey *et al.*, 1999], the deepest value would be -7.06 . The inverse correlation of this trend with CO₂ concentration is consistent with atmospheric trends for the later twentieth century [e.g., Friedli *et al.*, 1986]. However, this record may be affected by in situ CO₂ contributions in the firn profile, discussed below.

[15] The record for $\delta^{18}\text{O}$ in CO₂ is characterized by a gradual shift with depth to lower values, with a net difference between surface and the firn-ice transition depth of over 16‰. The direct measurement record of atmospheric CO₂ shows that $\delta^{18}\text{O}_{\text{CO}_2}$, normally controlled by exchange with seawater and leaf water, has a value of -1.4‰ and varied by less than 0.6‰ over the past several decades [Hopper *et al.*, 1998]. With the exception of the anomalous samples at 15.95, 30.33, and 32.85 m, discussed above, the observed depletion trend with depth can be attributed to exchange with the ice matrix ($-27.0 \pm 1.7\text{‰}$ VSMOW). This progressive exchange has been observed by Assonov *et al.* [2005] in firn air from three Antarctic sites, and shown to be a first-order reaction.

[16] The absence of a rapid negative shift in $\delta^{18}\text{O}_{\text{CO}_2}$ in the upper firn air column is evidence against contamination by summer melt layers. CO₂ affected by summer melting and refreezing has likely been lost to the open atmosphere by exchange through the upper convective firn air zone. An effect on the overall gradient of this trend by downward diffusion of CO₂ affected by melt layers can also be

considered. If nonnegligible, this effect would act to reduce the calculated rate constant (discussed below) from that expected for the in situ temperature of Devon firn. However, good comparison with rate constants for three sites with different temperatures in Antarctica [Assonov *et al.*, 2005] suggests that such an effect is negligible for Devon Island (Figure 6).

[17] The half-time of the CO₂-firn exchange reaction provides a tool to establish a chronology for firn air CO₂ throughout the column. Isotope exchange between CO₂ and the firn ice matrix occurs in conjunction with CO₂ exchange with the open atmosphere by diffusion through the firn air column. This diffusive mixing of firn air CO₂ broadens the distribution of ages and so the measured $\delta^{18}\text{O}$ of CO₂ at a given depth represents the average for a range of exchange times (ages). Average CO₂ ages can then be calculated from the measured $\delta^{18}\text{O}_{\text{CO}_2}$ values, providing a calibration point of known age can be identified. The sample containing the 1963 $^{14}\text{C}_{\text{CO}_2}$ peak meets this requirement, for which the average age can be fixed at 35 years (53.9 m depth, $\delta^{18}\text{O}_{\text{CO}_2} = -14.22\text{‰}$ VPDB). The exchange half-time can then be calculated from the difference between $\delta^{18}\text{O}_{\text{CO}_2}$ at this depth and the value for $\delta^{18}\text{O}_{\text{CO}_2}$ in equilibrium with the ice matrix, using an exponential decay equation:

$$A = A_0 e^{-\lambda t}, \quad (1)$$

where $A = \delta^{18}\text{O}_{\text{CO}_2(t)} - \delta^{18}\text{O}_{\text{CO}_2(\text{equil})}$, $A_0 = \delta^{18}\text{O}_{\text{CO}_2(\text{atm})} - \delta^{18}\text{O}_{\text{CO}_2(\text{equil})}$, $\lambda = \text{rate constant} = \ln 2 / T_{1/2}$, $T_{1/2} = \text{half-time of the exchange reaction}$, and $t = \text{period of exchange}$, in years.

[18] The $\delta^{18}\text{O}_{\text{CO}_2(t)}$ value is derived from the $^{18}\text{O}/^{16}\text{O}$ ratio in firn air CO₂ and $\delta^{18}\text{O}_{\text{CO}_2(\text{atm})}$ is the initial value at time $t = 0$. The value for $\delta^{18}\text{O}_{\text{CO}_2}$ in equilibrium with the ice

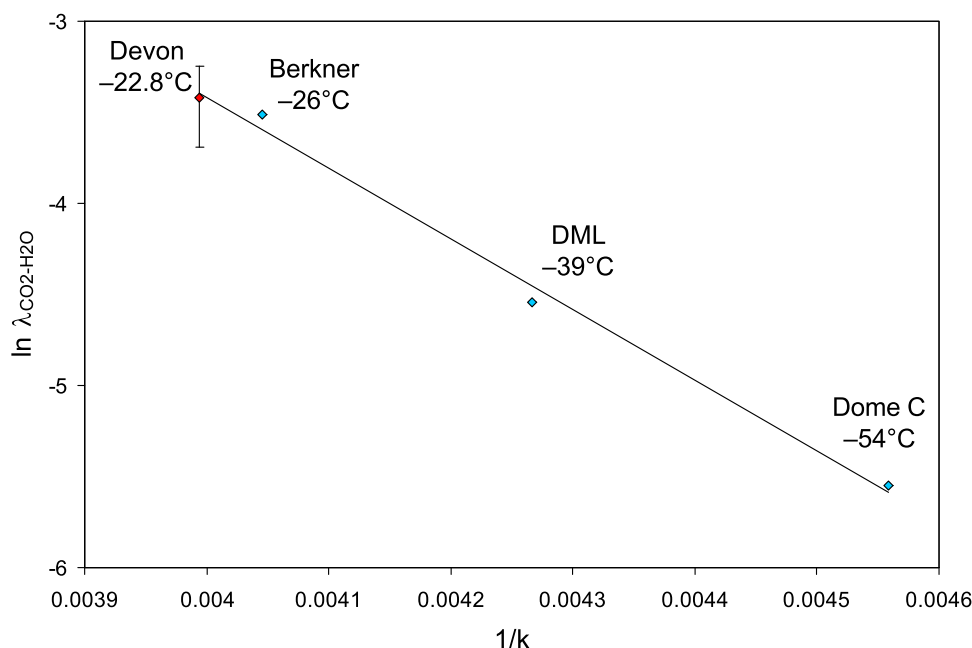

Figure 6. Correlation of firm temperature with rate of exchange of ¹⁸O in CO₂ with firm ice for Devon in comparison with three Antarctic sites [Assonov *et al.*, 2005]. For Devon, error bars are for λ_{CO₂-H₂O} = 0.03276 (+0.0062/−0.0078) on the basis of the uncertainty of the depth of the 1963 thermonuclear peak used to calibrate the exchange rate.

matrix ($\delta^{18}\text{O}_{\text{CO}_2(\text{equil})}$) is calculated from the combined fractionation factors for ¹⁸O exchange between CO₂ and water, between water and vapor, and between vapor and ice. This approach was used by Siegenthaler *et al.* [1988] to calculate the degree of ¹⁸O equilibrium between entrapped CO₂ and the ice matrix for Antarctic ice cores (South Pole, Siple, and Byrd Station):

$$\text{CO}_2 - \text{H}_2\text{O}_{\text{water}} : 10^3 \ln \alpha^{18}\text{O}_{\text{CO}_2-\text{wat}} = -0.0206(10^6\text{T}^{-2}) + 17.9942(10^3\text{T}^{-1}) - 19.97 \quad (2)$$

[Bottinga, 1968],

$$\text{H}_2\text{O}_{\text{water}} - \text{H}_2\text{O}_{\text{vapor}} : 10^3 \ln \alpha^{18}\text{O}_{\text{wat-vap}} = 1.137(10^6\text{T}^{-2}) - 0.4156(10^3\text{T}^{-1}) - 2.0667 \quad (3)$$

[Majoube, 1971],

$$\text{H}_2\text{O}_{\text{vapor}} - \text{H}_2\text{O}_{\text{ice}} : 10^3 \ln \alpha^{18}\text{O}_{\text{vap-ice}} = -11.839(10^3\text{T}^{-1}) + 28.782 \quad (4)$$

[Siegenthaler *et al.*, 1988].

Conversion for $\delta^{18}\text{O}$ of CO₂ measured against VPDB to the VSMOW scale is made with the conversion factor between VPDB-CO₂ and VSMOW- equilibrated CO₂ of 1.04142 established by Friedman and O'Neil [1977].

[19] Using the mean temperature for the firm profile in the Devon Island Ice Cap of $-22.8 \pm 0.1^\circ\text{C}$, and the average $\delta^{18}\text{O}$ value for the firm ice of -27.0‰ , the calculated $\delta^{18}\text{O}$ value for CO₂ in equilibrium with the ice becomes $\delta^{18}\text{O}_{\text{CO}_2(\text{equil})} = -20.18\text{‰}$. The $\delta^{18}\text{O}_{\text{CO}_2}$ of ambient air measured at Alert over the past several years is -1.4‰ VPDB [Hopper *et al.*, 1998]. The isotope exchange reaction

half-time can be determined by solving for $T_{1/2}$ in the exponential decay equation (1), using the 53.9 m sample containing the 1963 ¹⁴CO₂ peak. Here the average time t of exchange is 35 years, and the amount of exchange, A , is 5.97‰. Accordingly, for the firm temperature at Devon, the overall exchange reaction half-time is determined to be 21.2 years, and the rate constant, $\lambda = 0.0328 \text{ yr}^{-1}$.

[20] Considering the 3 m sampling interval used, and the asymmetry of the thermonuclear peak, the depth of the 1963 horizon cannot be constrained to better than ± 1.5 m. This uncertainty on the rate constant was calculated using interpolated $\delta^{18}\text{O}_{\text{CO}_2}$ values at 53.9 ± 1.5 m depth which were then assigned the 35-year age in equation (1), giving $\lambda = 0.0328 (+0.0062/-0.0078) \text{ yr}^{-1}$ and a reaction half-time in the range, $18.9 < T_{1/2} < 25.6$ years. Varying the values used for $\delta^{18}\text{O}_{\text{CO}_2(\text{atm})}$ or $\delta^{18}\text{O}_{\text{CO}_2(\text{equil})}$ by $\pm 1\text{‰}$ changes $T_{1/2}$ by only ± 2 years, well within the error on the depth of the 1963 peak.

[21] This rate constant was then used to generate the age profile for the firm air CO₂ and is presented in Figure 7. Error bars represent the uncertainty in the reaction half-time. Accordingly, firm air sampled at 59.94 m, just above the depth of occlusion, has an apparent CO₂ age of 56.7 (+6.0/−12.0) years. The offset in mean age between firm air CO₂ and the firm ice matrix increases from 22 years at 13 m depth to 84 years at the base of the firm air profile.

2.3. Firm Air Diffusion and Firm Diffusivity Using ¹⁴CO₂

[22] Atmospheric ¹⁴CO₂ provides an excellent analogue for the behavior of atmospheric CO₂ in firm air studies [Smith *et al.*, 2000]. ¹⁴CO₂ has diffusive properties that differ only marginally from those of CO₂ owing to its greater mass, and otherwise behaves the same as CO₂ in firm air. However, thermonuclear bomb tests from 1952 to

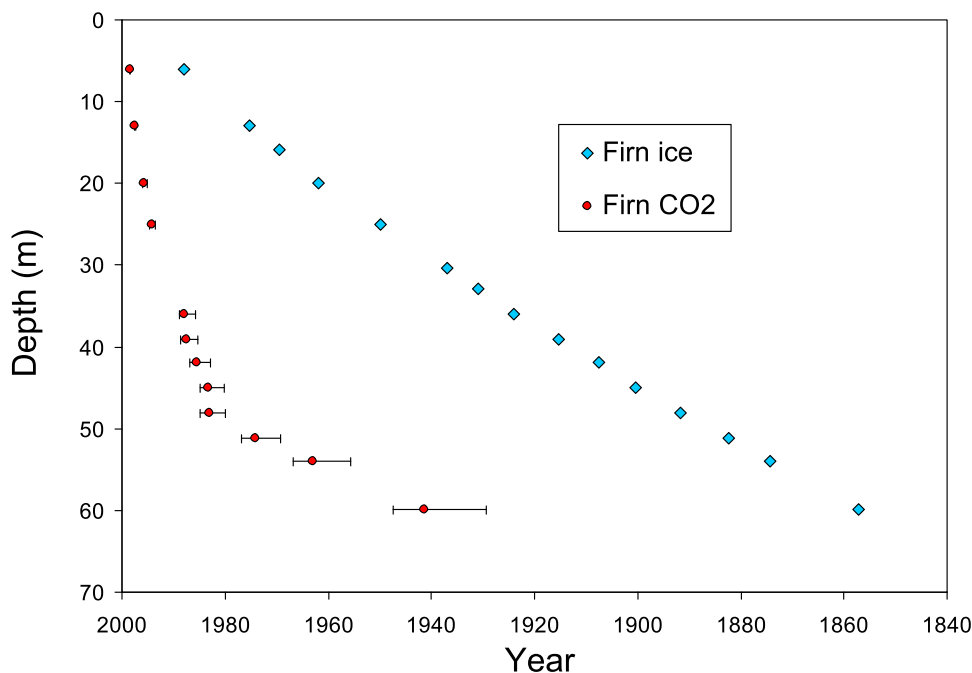

Figure 7. Reconstructions of the age structure of firn ice based on the rate of burial of the 1963 atmospheric tritium peak, and mean age of firn air based on ¹⁸O exchange between CO₂ and firn ice in the Devon 98-1 drill hole. Error bars based on the range in T_{1/2} from uncertainties in the depth of the 1963 peak (±1.5 m).

1962 and the subsequent American-Soviet atmospheric test ban treaty have created an atmospheric history of ¹⁴CO₂ that is greatly different from that of CO₂ concentration. The depth and shape of the pronounced 1963 ¹⁴CO₂ peak provides a valuable tool to assess firn air age. Further, the twofold increase in ¹⁴CO₂ in 1963 and subsequent attenuation to near background levels provides a robust atmospheric scenario from which to inversely model firn diffusivity.

[23] In this study, ¹⁴CO₂ is decoupled from CO₂ concentration, by normalizing its activity to concentration in firn air and thus expressing it as a mixing ratio. In this way, ¹⁴CO₂ can be modeled as an independent tracer. The routine extraction and analysis of ¹⁴CO₂ in air provides ¹⁴C activities normalized to mass carbon, and expressed as a percent of the activity of Modern Carbon (pMC). The ratio of ¹⁴C to total carbon in “Modern Carbon” has been determined to be 1.176E−12 by Karlen *et al.* [1968].

[24] Using this value, the mixing ratio of ¹⁴CO₂ (ppm) in the firn air samples can be calculated from the measured [CO₂] concentration (ppm) and the ¹⁴C activity of firn air CO₂ (*a*¹⁴C_{CO₂}). This is according to

$$^{14}\text{CO}_2 = 1.176\text{E} - 12 \cdot \frac{a^{14}\text{C}_{\text{CO}_2}}{100} \cdot [\text{CO}_2]. \quad (5)$$

The ¹⁴CO₂ profile in firn air from Devon was modeled using a 50-year atmospheric input scenario derived from the 1962 to 1993 record from Trondheim, Norway [Nydal and Lovseth, 1996], and extended to a full 1949–1998 record using a 50-year tree ring record from Kingston, Ontario [Kotzer and Watson, 2000] (Figure 8). Comparison with a tree ring record from Inuvik, Northwest Territories, Canada

(latitude 68°N [Battye, 2000]) and Vermont, Austria (latitude 47°N [Levin *et al.*, 1994]) shows less than 1 pMC variation with latitude.

[25] The atmospheric records and our firn air ¹⁴CO₂ measurements were first normalized to our measured atmospheric ¹³C values rather than the radiocarbon standard of −25‰, to provide true ¹⁴CO₂ concentrations. The extended atmospheric *a*¹⁴CO₂ (pMC) record was then normalized to an air-mixing ratio (ppm), according to equation (5), using the atmospheric CO₂ concentration record from the Mauna Loa observatory, Hawaii [Keeling and Whorf, 1998] (combined curve in Figure 8). The measurements of *a*¹⁴C (pMC) in firn air CO₂ from Devon were normalized to ¹⁴CO₂ (ppm) using our measured CO₂ concentrations (Table 1). The contributing effects of gravitational settling (+0.06 pMC at 60 m) and radioactive decay (−0.6 pMC at 35 years) were calculated to be less than the analytical uncertainty of ¹⁴CO₂.

[26] Expressed as a mixing ratio in the atmosphere, ¹⁴CO₂ (ppm) is uncoupled from the variable increase in CO₂ observed over the past 50 years. This allows modeling of ¹⁴CO₂ diffusion using its distinctive atmospheric scenario characterized by the sharp thermonuclear bomb peak of 1963 (Figure 8). This is a suitable scenario for modeling CO₂ diffusion in firn air, given the 30- to 50-year period for which firn air diffusion is active.

[27] A firn air diffusion model [Rommelaere *et al.*, 1997] was used in an inverse modeling exercise to calibrate the firn diffusivity profile with the measured ¹⁴CO₂ profile (ppm normalized) in the firn air. Reduced diffusion of ¹⁴CO₂ with respect to ¹²CO₂ due to the mass difference (as described by Trudinger *et al.* [1997]), is accounted for by the model. A firn diffusivity profile (Figure 9) was

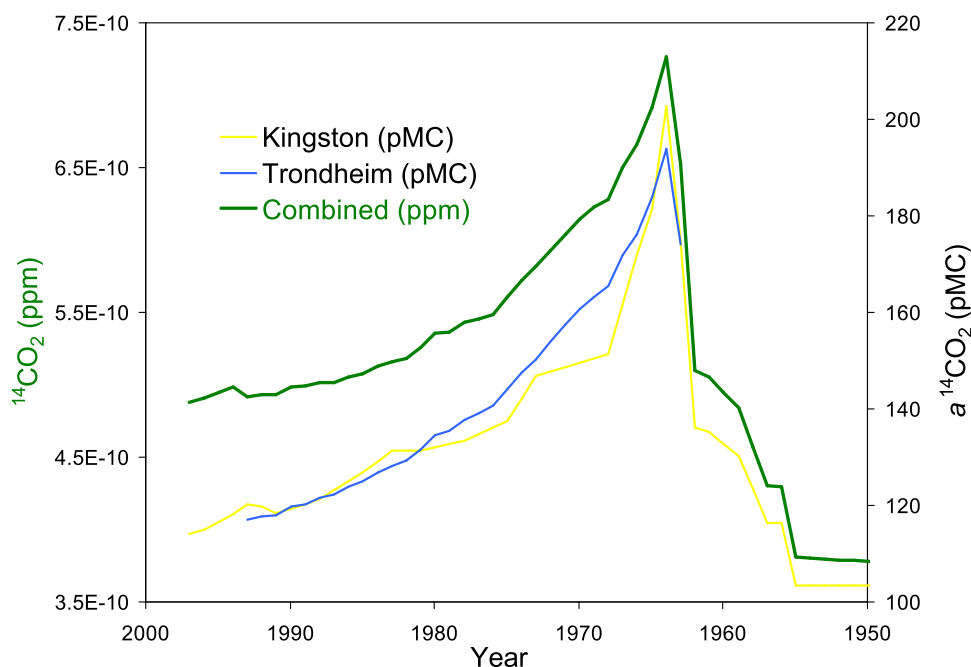

Figure 8. Combined atmospheric scenario for $^{14}\text{CO}_2$ (ppm) derived from the Trondheim atmospheric $^{14}\text{CO}_2$ record [Nydal and Lovseth, 1996] and the Kingston, Ontario, tree ring ^{14}C record [Kotzer and Watson, 2000]. Combined scenario is normalized to the $^{14}\text{CO}_2$ mixing ratio in air (ppm) using the Mauna Loa CO_2 record [Keeling and Whorf, 1998] and corrected to atmospheric ^{13}C [Hopper et al., 1998].

produced with the model by iteratively modifying the diffusivity profile until a visual match between the modeled and measured 1998 $^{14}\text{CO}_2$ profile was achieved (Figure 10).

[28] The resulting diffusivity profile exhibits the three zones identified by Schwander [1996]. Values in the uppermost zone of convection decrease from 16.3 to about $14.6 \text{ mm}^2 \text{ s}^{-1}$ in the first 10 m. The intermediate diffusive zone extends to about 45 m depth, where diffusivity values

decrease to less than $0.15 \text{ mm}^2 \text{ s}^{-1}$. The nondiffusive zone, with diffusivities from 0.016 to $0.0003 \text{ mm}^2 \text{ s}^{-1}$, extends from 50 m to 60 m. Below this depth the horizontal permeability was too low to permit flow of firn air to the sample zone below the packer.

[29] This diffusivity profile is substantially lower than for diffusivities published for dry firn sites, consistent with Fabre et al. [2000], who compare laboratory measurements

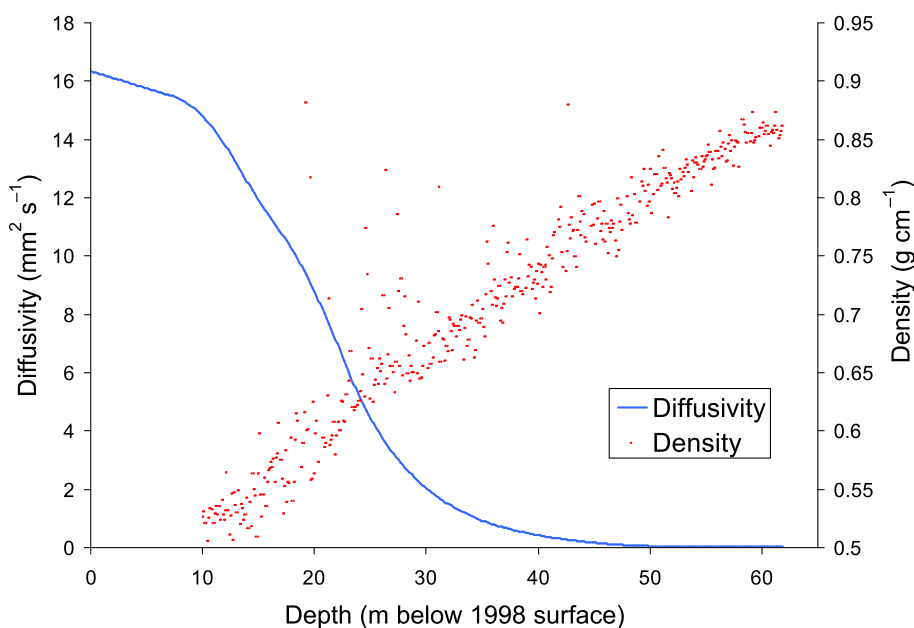

Figure 9. Diffusivity profile for Devon Ice Cap firn, produced by inverse modeling with $^{14}\text{CO}_2$, shown with density data measured on the Devon 98-1 core.

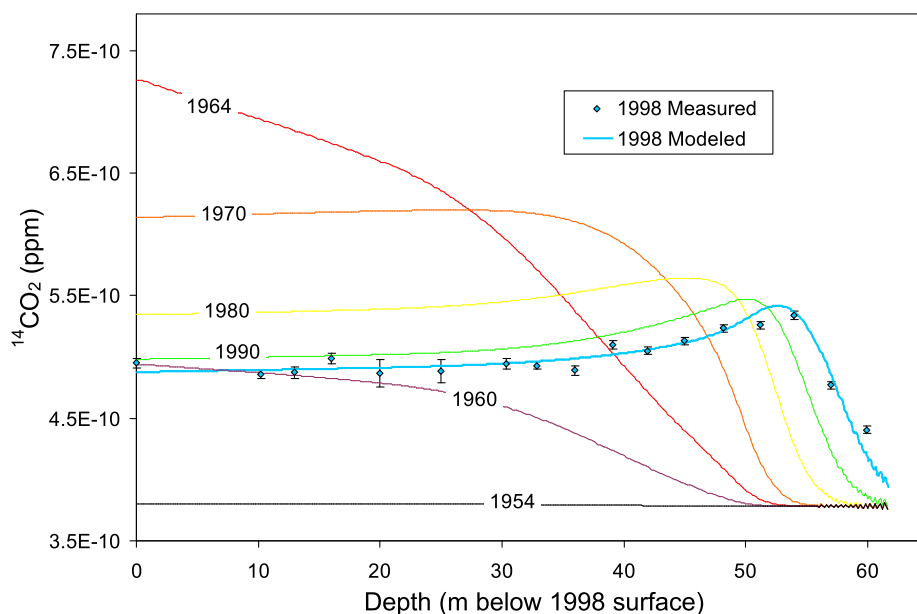

Figure 10. Modeled 1998 $^{14}\text{CO}_2$ profile compared with measured values from firn air in the Devon 98-1 core hole, together with modeled profiles for earlier decades showing the evolution of the $^{14}\text{CO}_2$ profile since the period of atmospheric tests.

of effective diffusivity with inverse modeling results obtained from gas mixing ratios. They show that the Devon site has effective diffusivities on the order of 20 to 30% of those for mild (Dronning Maud Land and Law Dome) and cold sites (Dome C and Vostok). This low diffusivity characterizing Devon Island firn can be attributed to the presence of ice layers which significantly reduces vertical diffusion.

[30] Following calibration of the diffusivity profile, diffusion was then modeled using a sequence of atmospheric scenarios for $^{14}\text{CO}_2$ evolving at 10-year intervals between 1950 and 1990. This allows visualization of the downward diffusion and burial of the 1963 thermonuclear peak (Figure 10). The mixing ratio of $^{14}\text{CO}_2$ prior to 1950 was assumed to be constant and equal to a pre-industrial value of $3.76\text{E}-10$ ppm. The 1964 scenario shows the rapid downward diffusion of $^{14}\text{CO}_2$ following the dramatic atmospheric increase in 1963. By 1970, however, the $^{14}\text{CO}_2$ gradient in firn air has reversed, and net upward diffusion occurs owing to the attenuation of the $^{14}\text{CO}_2$ peak in the open atmosphere by exchange with terrestrial carbon and marine CO_2 . High concentrations of $^{14}\text{CO}_2$ remnant from the 1963 peak are preserved in firn air only in the nondiffusive zone, where systematic burial of the peak begins to take place. The very low values for firn diffusivity required to preserve the 1963 thermonuclear peak clearly preclude significant vertical diffusion in firn below a depth of 50 m.

[31] The diffusivity profile generated from the ^{14}C atmospheric scenario then tested using reconstructed atmospheric scenarios for CH_4 and CO_2 . These were produced from measured concentrations at Alert, Nunavut (for CH_4 from 1986 to 1993 from *Dlugokencky et al.* [1994], and for 1991 to 1998 from *Steele et al.* [2002]; for CO_2 from 1976 from *Keeling and Whorf* [2005]), extrapolated to 1950 using the global atmospheric records [*Ehhalt and Prather*, 2001; *Prentice*, 2001] and amplified by the difference between

Alert and global concentrations during the 1986 to 1998 overlap period (Figures 11a and 11c).

[32] Diffusion modeling provides a reasonable fit to the measured CH_4 profile (Figure 11b). The deviation to higher measured CH_4 concentrations in the shallowest firn zone is likely due to diffusion of the strongly seasonal CH_4 signal ($\pm\sim 70$ ppbv with a maximum in late autumn) to depths of 15 m or more. By contrast, the modeled CO_2 profile poorly represents the measured concentrations. This suggests that the atmospheric scenario generated from measurements at Alert may under represent CO_2 levels at Devon over this period. In addition, contributions from dust and organics [*Delmas*, 1993; *Monnin et al.*, 2001; *Kramer Campen et al.*, 2003] is known to contaminate Northern Hemisphere ice sheets and may have contributed to an excess in CO_2 .

[33] Despite the greater diffusivity for CH_4 , the firn air profile provides a good match with atmospheric concentrations for years corresponding to the firn air CO_2 ages. A plot of the measured CH_4 concentrations in firn air samples against the atmospheric scenario CH_4 concentration (Figure 11) for the year corresponding with the $\delta^{18}\text{O}_{\text{CO}_2}$ age of the sample (Figure 7), produces close to a 1:1 correlation (Figure 12). Slight enrichments for the measured CH_4 concentrations likely reflect the greater diffusivity of CH_4 over CO_2 .

3. Conclusions

[34] Melt layers in ice sheets have been considered problematic for firn air and entrapped gas studies owing to the potential for contamination of the atmospheric signal by dissolution and exsolution during melt-refreeze cycles. On the other hand, firn profiles with horizontal melt layers could potentially enhance the preservation of atmospheric gas records by reducing vertical diffusivity.

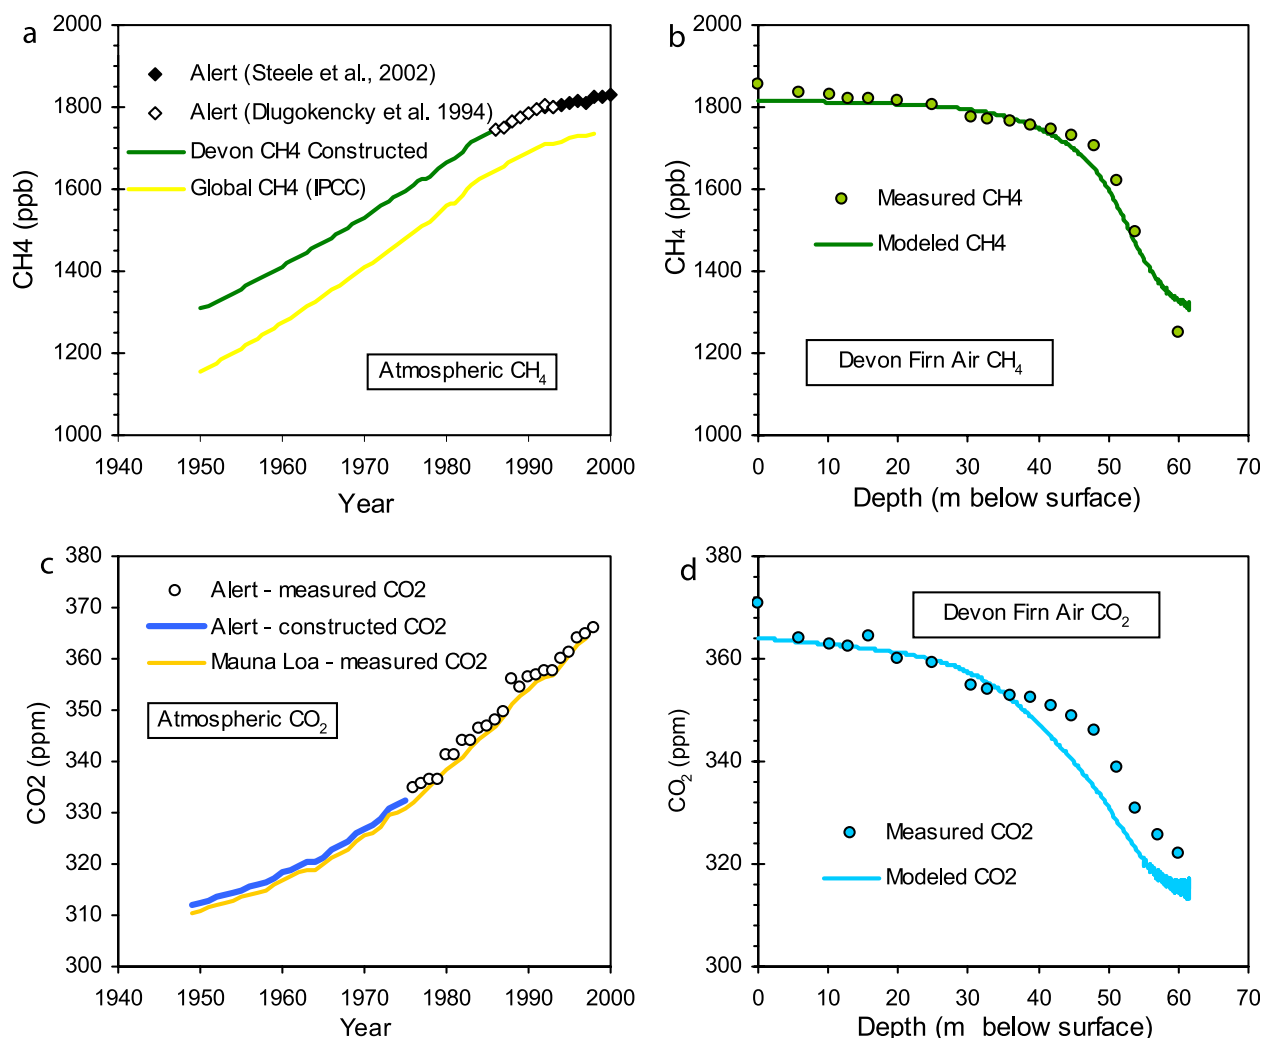

Figure 11. (a, c) Atmospheric scenarios derived from measured values from Alert, Nunavut (1986–1993 [Dlugokencky et al., 1994]; 1991–1998 [Steele et al., 2002; Keeling and Whorf, 2005]), for CH₄ and CO₂, respectively. The records constructed for the period prior to measurements at Alert are derived from the global atmospheric record (Ehhalt and Prather [2001] for global CH₄ and Keeling and Whorf [1998] for CO₂ at Mauna Loa extrapolated to 1950) with an amplification for high-latitude values derived from the difference between measured Alert and global concentrations. (b, d) Modeled depth profiles compared with measured values from firn air in the Devon 98-1 core hole, for CH₄ and CO₂, respectively.

[35] The $\delta^{18}\text{O}_{\text{CO}_2}$ values measured for the uppermost firn air CO₂ retain an open atmospheric signal with no evidence for alteration by exchange with water from summer melting. The rapid exchange of gas between the shallow firn air and the open atmosphere that occurs on a multiannual basis has diluted to negligible amounts any CO₂ affected by summer melting and refreezing. This suggests that firn profiles with summer melt layers can reliably preserve atmospheric trace gas signals. However, the melt layers themselves may include occluded gases that could potentially affect the older atmospheric record derived from gas bubbles in ice cores sampled by dry extraction methods.

[36] The 1963 thermonuclear bomb peak for ¹⁴CO₂ has been recovered in air samples from the permeable firn of the Devon Island Ice Cap, and provides a useful trace gas with a strong atmospheric anomaly to model firn diffusivity for an

ice sheet with summer melting. The diffusivity profile produced by inverse modeling of the ¹⁴CO₂ mixing-ratio profile clearly shows the three zones identified by Schwander [1996]. Firn diffusivity values are high in the uppermost zone of convection. The intermediate zone extends to about 45 m depth, with diffusivity values less than 0.15 mm²s⁻¹. The nondiffusive zone extends from below 50 m to 60 m with diffusivities from 0.016 to 0.0003 mm²s⁻¹.

[37] Fabre et al. [2000] also find much lower diffusivity values for Devon firn. However, inverse modeling of the ¹⁴CO₂ peak indicates that the zone below 50 m depth has considerably lower diffusivity than those determined by modeling the atmospheric CO₂ mixing ratio. This may be an artifact of the much stronger ¹⁴CO₂ signal over that for the CO₂ mixing ratio which provides a better constraint for modeling the deeper diffusivity profile.

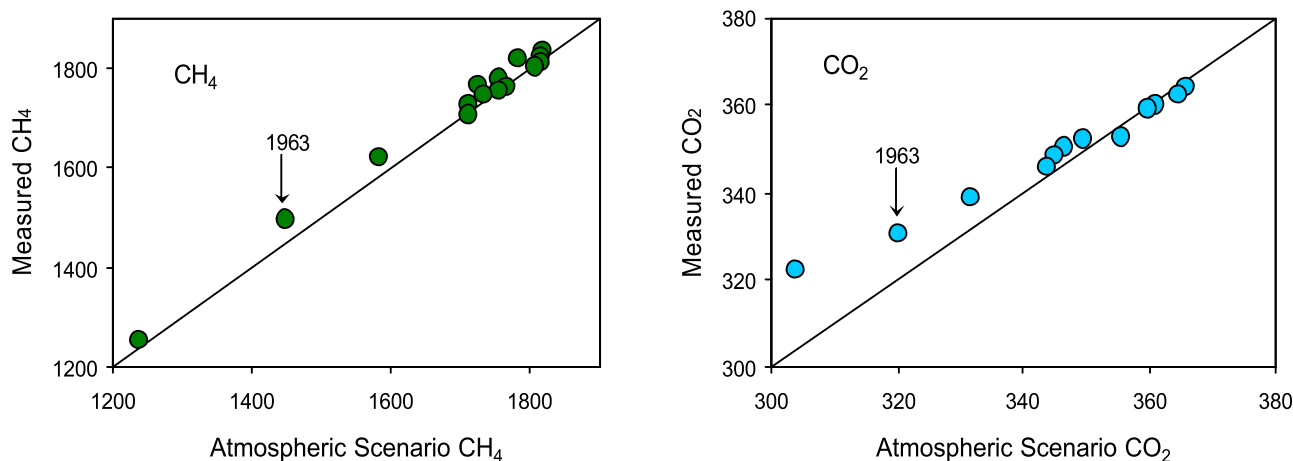

Figure 12. Measured CH₄ and CO₂ for samples versus CH₄ and CO₂ concentrations corresponding to $\delta^{18}\text{O}_{\text{CO}_2}$ ages. Samples with age inversions (15.95 m, 30.33 m, and 3.85 m; Figure 6) are not included. Enrichments in measured CH₄ likely reflect its enhanced diffusion over CO₂. Enrichments in measured CO₂, as discussed in text, may reflect uncertainties in the atmospheric scenario reconstructed for Devon and possible in situ CO₂ production.

[38] Modeled CH₄ and CO₂ firn air profiles were produced with this diffusivity profile using atmospheric scenarios reconstructed from measurements at Alert, Nunavut, and global trends. For CH₄ a reasonable fit to measured concentrations is produced. A poor fit is found for CO₂ where the modeled diffusion profile under predicts concentrations in the intermediate and nondiffusive zones, possibly reflecting in situ contributions from impurities and/or a poorly constrained atmospheric scenario at Devon.

[39] A profile of average CO₂ age has been produced using the extent of ¹⁸O exchange between firn air CO₂ and firn ice on Devon. This chronology is based on the reaction half-time of 21.2 years (rate constant of 0.0328 yr⁻¹), calibrated using the firn air sample at 53.94 m, which preserves the 35-year-old (in 1998) thermonuclear ¹⁴CO₂ peak from 1963. This gives firn air CO₂ sampled at 59.94 m, just above the depth of occlusion an age of 56.7 (+6.0/−12.0) years. Firn ice at this depth has an age of 140 years derived from the accumulation rate based on the depth of the 1963 tritium peak, corresponding to accumulation in 1858. This gives an age offset for firn ice and firn air CO₂ at the point of occlusion of 85 years. Despite the difference in diffusivity, a good fit between measured CH₄ concentrations in firn air samples and atmospheric CH₄ concentrations for the years corresponding to equivalent $\delta^{18}\text{O}_{\text{CO}_2}$ ages. Given the ease of access to such low-altitude ice sheets as Devon and others in the Canadian Arctic, firn profiles with summer melting can provide a useful archive of trace gas records.
