Atmospheric methane (CH₄) records reconstructed from polar ice cores represent an integrated view on processes predominantly taking place in the terrestrial biogeosphere. Here, we present dual stable isotopic methane records [$\delta^{13}\text{C}_{\text{CH}_4}$ and $\delta\text{D}(\text{CH}_4)$] from four Antarctic ice cores, which provide improved constraints on past changes in natural methane sources. Our isotope data show that tropical wetlands and seasonally inundated floodplains are most likely the controlling sources of atmospheric methane variations for the current and two older interglacials and their preceding glacial maxima. The changes in these sources are steered by variations in temperature, precipitation, and the water table as modulated by insolation, (local) sea level, and monsoon intensity. Based on our $\delta\text{D}(\text{CH}_4)$ constraint, it seems that geologic emissions of methane may play a steady but only minor role in atmospheric CH₄ changes and that the glacial budget is not dominated by these sources. Superimposed on the glacial/interglacial variations is a marked difference in both isotope records, with systematically higher values during the last 25,000 y compared with older time periods. This shift cannot be explained by climatic changes. Rather, our isotopic methane budget points to a marked increase in fire activity, possibly caused by biome changes and accumulation of fuel related to the late Pleistocene megafauna extinction, which took place in the course of the last glacial.

atmosphere | methane | megafauna | ice core | stable isotopes

Past variations of the atmospheric methane mixing ratio ([CH₄]) have been documented using ice cores on various timescales (1–5). Compared with preindustrial levels of 715 parts per billion (ppb) (6, 7), anthropogenic emissions have led to a 2.5-fold increase since about the year 1800 CE as documented by the National Oceanic and Atmospheric Administration Earth System Research Laboratory. The lowest values of around 360 ppb are measured in ice cores during glacial maxima, whereas for the last eight interglacials, [CH₄] typically ranged between 600 and 700 ppb (4). Fast and significant stadial/interstadial [CH₄] increases occurred within a few decades during glacials in parallel to Dansgaard-Oeschger events (8). Furthermore, [CH₄] levels in the Northern Hemisphere are mostly higher than those in the Southern Hemisphere (9). These data taken together with our understanding of the present day methane budget (10–15) show that wetlands and primarily those located in the tropics dominate natural CH₄ emissions. On long timescales, wetland extent (16) and CH₄ fluxes are also strongly influenced by the position of the Intertropical Convergence Zone (ITCZ) (17) and the global monsoon system (18, 19), which in turn, is steered by changes in solar insolation. There is an ongoing debate on the relative contributions from tropical vs. boreal wetlands (ref. 9 and references therein). The latter is possibly overestimated, because other high-latitude sources, like thawing permafrost, thermokarst lakes (20), or (cryospherically capped) geologic seeps (21), also contribute to this source from a hemispheric (ice core) point of view.

Additional constraints on the contribution of the various methane sources can be derived from the carbon and hydrogen stable isotopic signature of CH₄ in ice cores. Microbially produced CH₄ is

depleted in both stable isotopologues (¹³C and ²H or D; “light” isotopic sources) compared with the source mix. However, there are two important natural sources relatively enriched in ¹³C and D (“heavy” sources): biomass burning (BB), an important and climatically variable process (22–26), and “geologic” emissions of old methane (GEMs; called GEM by, for example, refs. 27–29).

Accordingly, the isotopic fingerprint of methane has been successfully used to shed light on relative source mix changes (30–33). However, biogenic sources (such as wetlands and BB) may change their isotopic signatures in parallel to changing climate and environmental conditions (25, 34). For the last glacial, Möller et al. (25) showed that the ¹³C content of CH₄ ($\delta^{13}\text{C}_{\text{CH}_4}$) is higher at low CO₂ levels and concluded that biome changes play a major role in this isotopic change. The deuterium content of CH₄ [$\delta\text{D}(\text{CH}_4)$] is also a function of the isotopic signature of the water used for methanogenesis (31, 35–38). However, the net impact of global meteoric water isotope changes caused by the transfer of water from the ocean to ice sheets is only of secondary importance (refs. 31 and 36 and references therein). Both $\delta^{13}\text{C}_{\text{CH}_4}$ and $\delta\text{D}(\text{CH}_4)$ are influenced by at least one other factor, namely the ratio of net to gross CH₄ production in wetlands (i.e., the fraction of CH₄ consumed by methanotrophs before emission to the atmosphere). This process varies as a function of the water table and site conditions, leading to changes in strength and isotopic composition of CH₄ emissions (31, 39).

Significance

Polar ice is a unique archive of past atmosphere. Here, we present methane stable isotope records (used as source fingerprint) for the current and two past interglacials and their preceding glacial maxima. Our data are used to constrain global emissions of methane. Tropical wetlands and floodplains seem to be the dominant sources of atmospheric methane changes, steered by past variations in sea level, monsoon intensity, temperature, and the water table. In contrast, geologic emissions of methane are stable over a wide range of climatic conditions. The long-term shift seen in both isotopes for the last 25,000 y compared with older intervals is likely connected to changes in the terrestrial biosphere and fire regimes as a consequence of megafauna extinction.

Author contributions: M.B., J.S., and H.F. designed research; M.B., J.S., and B.S. performed research; M.B. and J.S. contributed new reagents/analytic tools; M.B., J.S., J.B., and H.F. analyzed data; M.B. performed methane box modeling; J.B. performed methane box modeling and firn diffusion correction; M.B., J.S., J.B., and H.F. prepared the discussion of results; and M.B., J.S., J.C., and H.F. wrote the paper.

In this contribution, we greatly extend the existing carbon and hydrogen isotopic information of CH₄ from ice cores in terms of temporal coverage, temporal resolution, accuracy, and precision. Our data cover three interglacials and their preceding glacial terminations and glacial maxima. The interpretation of these data centers around the discussion of the source side of the methane cycle. This assumption is justified in the light of recent work on sinks of methane (40–43), with net variations that are estimated to be relatively small (*SI Text*). Hence, dual stable isotope records of methane provide important insights into the suite of terrestrial and marine processes emitting methane and their changes in the past.

Ice Core Measurements

We measured records of methane stable carbon ($\delta^{13}\text{CH}_4$) and hydrogen [$\delta\text{D}(\text{CH}_4)$] isotopes from four Antarctic ice cores (Fig. 1 and Figs. S1 and S2–S5): i.e., the two European Project for Ice Coring in Antarctica (EPICA) ice cores from Dronning Maud Land (EDML) and from Dome Concordia (EDC), the Talos Dome [Talos Dome Ice Core Project (TALDICE)], and the Vostok (core 5G; Vostok Station) ice cores. Note that these values are representative of the tropospheric isotope signature of methane in high southern latitudes and that an inter-polar difference (IPD) in [CH₄] and its isotopic signatures exists.

The investigated time periods are from 25 to 0.5 kilo years (ka) before present [(BP), where present refers to 1950], from 160 to 80 ka BP, and from 440 to 370 ka BP (Fig. 1 and Fig. S1). With reference to marine sediment records, these time periods are approximately equivalent to Marine Isotope Stage (MIS) 2&1, MIS 6&5.5, and MIS 12&11.3, respectively (44, 45).

The $\delta^{13}\text{CH}_4$ data were measured on the TALDICE (170 samples) and EDC (90 samples) ice cores and using seven samples from Vostok for MIS 5.5. For $\delta\text{D}(\text{CH}_4)$, we present data from EDML (54 samples) for MIS 2&1 and MIS 5.5 and from EDC (47 samples) for MIS 6&5.5 and MIS 12&11.3. Altogether, this dataset presents dual stable isotope records from three glacial maxima, the following terminations and interglacials, and two glacial inceptions.

Information on measurement procedures, accuracy, and precision can be found in *Materials and Methods* and our technical papers (46–48). $\delta^{13}\text{CH}_4$ and $\delta\text{D}(\text{CH}_4)$ data are reported using the δ notation on the international Vienna Pee Dee Belemnite (VPDB) and Vienna Standard Mean Ocean Water (VSMOW) scales, respectively. Information on data handling with respect to firn diffusion effects is described in *SI Text*.

Results

The main results of this study, presented in Fig. 1 and Fig. S1, confirm previous results but largely extend the time coverage and are based on data with improved precision and accuracy (46–48). Our results are consistent with $\delta^{13}\text{CH}_4$ data from Greenland Ice Sheet Project 2 (GISP2) (49) and EDML (32) for the Holocene (MIS 1), the last termination, and the last glacial maximum (LGM) (Fig. 1 and Figs. S3 and S6), as well as throughout the last glacial period (25) (Fig. S1). For the last 25 ka, we present a greatly improved view of the evolution of $\delta\text{D}(\text{CH}_4)$ compared with the pioneering work by Sowers (31, 49), which was characterized by higher sample to sample variability (Fig. S6).

In our data, we document a rather smooth deglacial $\delta\text{D}(\text{CH}_4)$ decrease of 18‰ and only small long-term variations over the Holocene, with a mean value of -71 ‰ for the Southern Hemisphere. Note that there is a north–south IPD for $\delta\text{D}(\text{CH}_4)$ of roughly -16 ‰ for the Holocene (46). Interestingly, glacial/interglacial amplitudes in $\delta\text{D}(\text{CH}_4)$ can be either of similar amplitude (LGM–Holocene: ~ 14 ‰) as swings from stadial to interstadial conditions (e.g., during the glacial inception around 390 ka BP in Fig. 1) or considerably larger (MIS 6–MIS 5: ~ 25 ‰). The decrease of $\delta\text{D}(\text{CH}_4)$ into MIS 5.5 is also faster compared with the much

smoother MIS 2/1 and MIS 12/11.3 transitions. On the contrary, all of the $\delta^{13}\text{CH}_4$ transitions investigated are gradual (Figs. S3–S5).

Within full glacial periods and interglacials, $\delta\text{D}(\text{CH}_4)$ shows rather small variations [standard deviation (SD) is typically around 5‰ (Table S1)] compared with the large leverage of sources and sinks, indicating little changes in the source composition. On the contrary, $\delta^{13}\text{CH}_4$ shows pronounced trends that differ for all of the interglacials investigated. Most importantly, interglacial $\delta^{13}\text{CH}_4$ is not correlated to [CH₄]. Next, while for $\delta\text{D}(\text{CH}_4)$ and $\delta^{13}\text{CH}_4$, the interglacial MIS 5.5 and MIS 11.3 mean levels are comparable, a clear shift of the mean values for the Holocene is evident (Fig. 1 and Fig. S2). A shift of similar size is also found for the mean level during the LGM compared with MIS 6 and MIS 12 (Fig. 1 and Table S1).

Our data confirm earlier findings (25, 49) that $\delta^{13}\text{CH}_4$ is evolving independently from [CH₄] for large parts of the ice core record. This feature is substantiated by new $\delta^{13}\text{CH}_4$ data from EDC over the MIS 12/11.3 transition and the penultimate glacial termination as well as for variations during MIS 11.3. In all of the terminations investigated, $\delta^{13}\text{CH}_4$ drops strongly when [CH₄] increases only slowly, well before the major rapid [CH₄] rise (Fig. 1 and Figs. S3–S5). Only about one-half of the amplitude of the $\delta^{13}\text{CH}_4$ change is covariant with the rapid methane rises into the interglacial periods. The decoupling between $\delta^{13}\text{CH}_4$ and [CH₄] is even more evident during rapid CH₄ rises connected to Dansgaard–Oeschger (DO) events, which have no counterpart in $\delta^{13}\text{CH}_4$. This observation is indicative of small source mix changes (25). Moreover, there is no abrupt $\delta^{13}\text{CH}_4$ shift connected to the [CH₄] peak during the early MIS 5.5 (128.5 ka BP) (Fig. 1). On the contrary, $\delta^{13}\text{CH}_4$ continues its downward trend during MIS 5.5, when [CH₄] decreases toward lower glacial values, whereas [CO₂] and $\delta^{15}\text{N}_2$ in ice cores (a proxy for firn temperature) indicate interglacial conditions (50, 51). $\delta^{13}\text{CH}_4$ only reverses its trend around 115 ka BP when [CO₂] and $\delta^{15}\text{N}_2$ start to drop (Fig. S4). At that point in time, [CH₄] is already below 500 ppb, a level typical of stadial intervals.

To confirm the very low $\delta^{13}\text{CH}_4$ values of our EDC and TALDICE records at the end of MIS 5.5 (which were not seen in the very few Vostok samples previously measured at Pennsylvania State University and presented in ref. 25), we analyzed an additional seven samples from the Vostok core with our improved method. These samples correspond well to our data from other ice cores (Fig. 1 and Fig. S4), thus indicating that the lowest values for $\delta^{13}\text{CH}_4$ of -52 ‰ must have been missed in the older Vostok record (25), most likely because of methodological problems. Other small differences in our record compared with the older Vostok time series are presented in figure 9 of ref. 47, but the overall conclusions of ref. 25 are confirmed in the light of the improved dataset presented here (Fig. 1 and Fig. S1).

Discussion

The Potential of Marine Clathrates and Other Geologic CH₄ Emissions.

Decreasing $\delta\text{D}(\text{CH}_4)$ over all three glacial terminations (Fig. 1) supports the conclusion in refs. 31 and 36 that marine clathrates (gas hydrates) do not significantly contribute to the altered atmospheric CH₄ budget during transitions. However, it is not only catastrophic emissions caused by destabilization events of marine clathrates that have been proposed to explain past [CH₄] variations (52, 53) but also, more steady emissions through, for example, natural marine hydrocarbon seeps that may have been exposed during times of sea-level low stands. Together with seeps and mud volcanoes, clathrate releases constitute the so-called GEM (27, 28, 54). Concerning the modern Arctic, there is also an ongoing debate on the origin and importance of CH₄ releases from the East Siberian Shelf (55–59), which are thought to stem from both organic carbon in thawing subsea permafrost and geologic reservoirs.

In the following section, we show that our isotope data (Fig. 1) are incompatible with the strong role of GEM proposed by, for

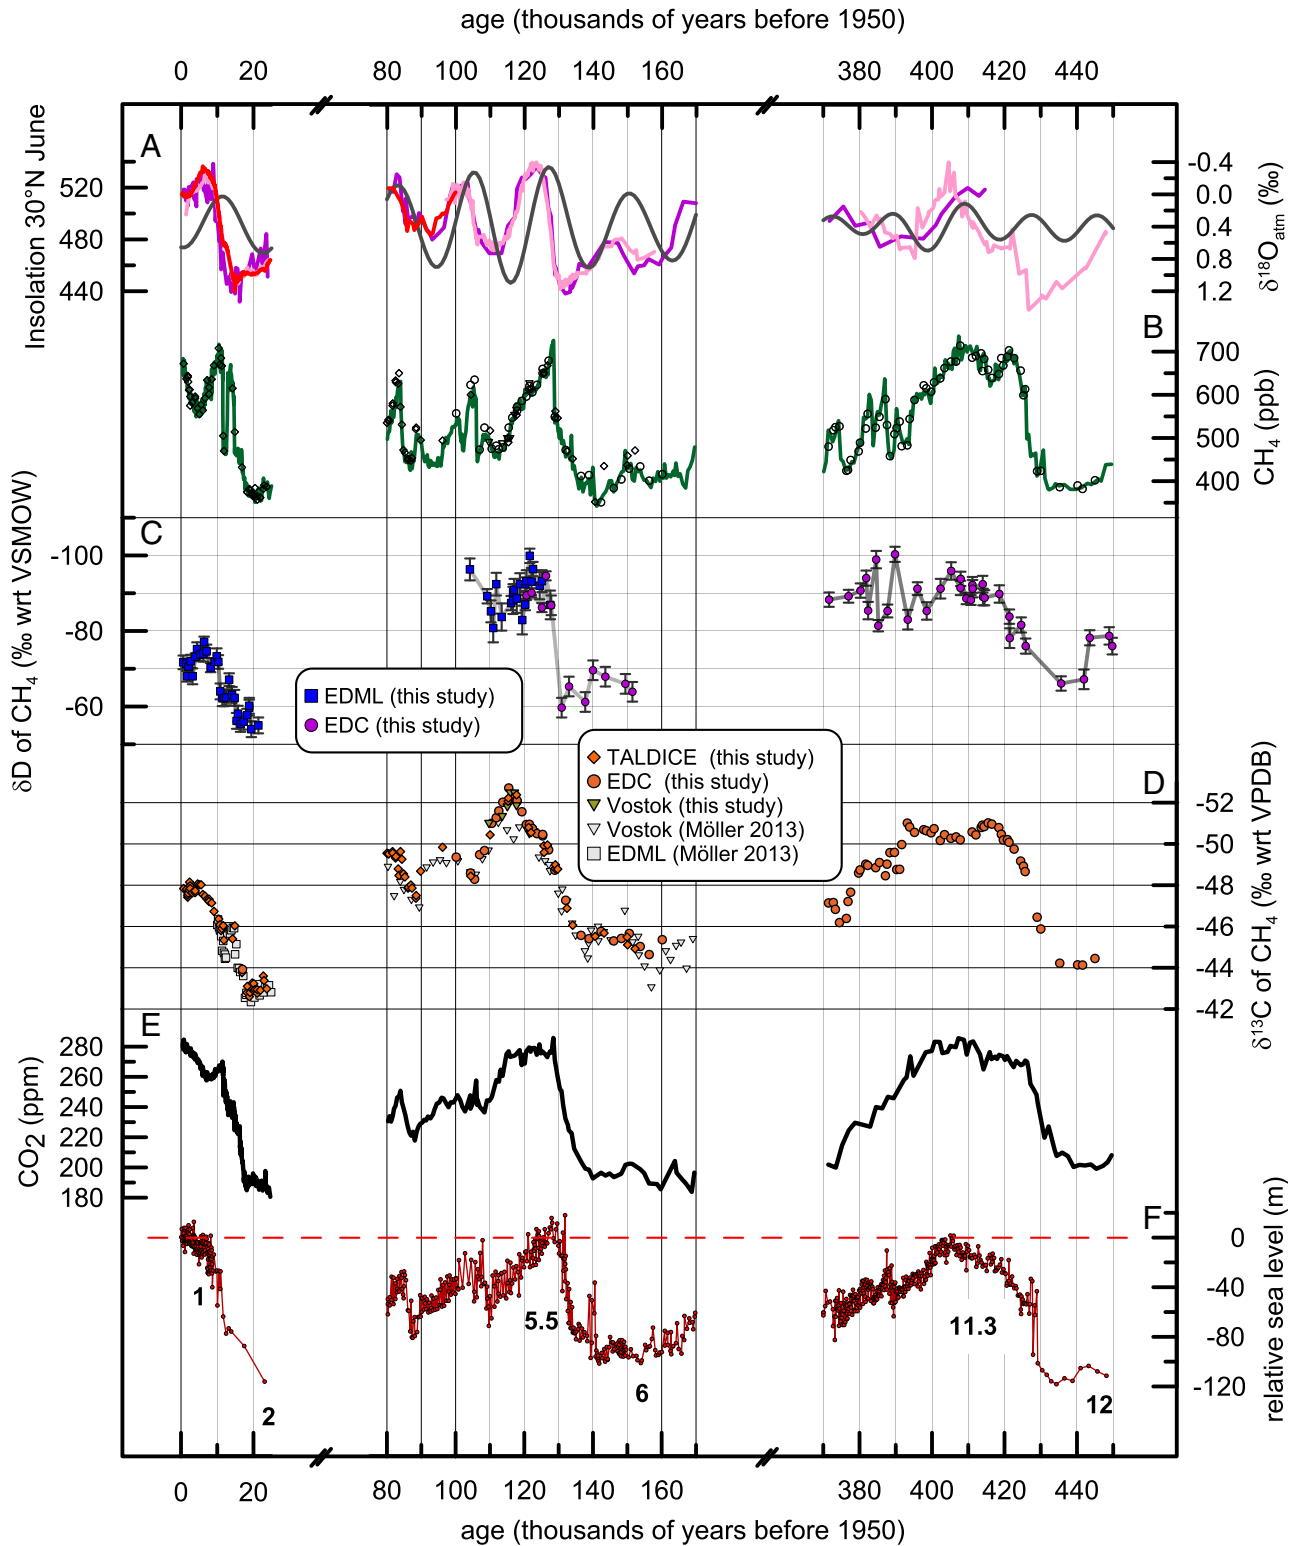

Fig. 1. Paleoclimatic records for three interglacials and preceding glacial maxima (note the breaks in the x axis). From top to bottom, the panels show (A) solar insolation in June at 30° N (133) and atmospheric $\delta^{18}\text{O}$ from Vostok (purple) (134), EDC (light pink) (51, 135–138), and Siple Dome (red) (84); (B) $[\text{CH}_4]$ (ref. 4 and data from this study); (C) $\delta\text{D}(\text{CH}_4)$ from EDML and EDC (this study; error bars are 1-sigma SDs of reference air measurements); (D) $\delta^{13}\text{C}$ of CH_4 from Talos Dome, EDC, and Vostok (5G; this study; the error [based on 1-sigma SDs of replicate ice core measurements (47)] is approximately the size of the symbols) and data from EDML and Vostok (25, 32); (E) $[\text{CO}_2]$ (110); and (F) relative sea level as reconstructed from Red Sea sediment cores (108). Time intervals indicative of MIS (45) are given next to the sea-level curve. Ice core records are given on the Antarctic ice core chronology (AICC2012) gas age scale (137, 139), and insolation and sea level on their individual age scales. Note the inverse direction of all isotope axes.

example, refs. 29, 60, and 61. Luyendyk et al. (61) argue that lowered methane concentrations along with high $\delta^{13}\text{CH}_4$ values during the glacial could be a result of increased GEM, whereas wetland emissions were reduced to a minimum. However, our $\delta\text{D}(\text{CH}_4)$ constraint indicates that this hypothesis is incorrect for two reasons. First, the differences in $\delta\text{D}(\text{CH}_4)$ between glacial and interglacials are too small to be compatible with a dominant GEM source, and second, a covariation (e.g., within MIS 5.5) of $\delta^{13}\text{CH}_4$ and $\delta\text{D}(\text{CH}_4)$, expected under the dominant GEM hypothesis, is not seen in our data (Fig. 1 and Figs. S2–S5). An unambiguous assessment of the geologic emissions based on $^{14}\text{CH}_4$ measurements performed on Antarctic ice over the last termination is pending, but results presented by Petrenko et al. (62) indicate only a 10% contribution from GEM to the atmospheric methane budget during the Younger Dryas period and no strengthening of this source for the $[\text{CH}_4]$ rise into the Preboreal.

To quantify the maximum contribution of GEM based on our data, we used our previously described box model (32, 36). However, to be consistent with work on the recent atmospheric methane budget (63), we differentiated only three source categories (microbial, GEM, and BB). Emissions and isotopic signatures of these three sources were varied in our model within predefined limits in a Monte Carlo approach. Moreover, we also included a CI sink for CH_4 in the marine boundary layer. Equilibrium results of each model run were compared with the ice core constraints (Table S1), and 10,000 valid runs were recorded for each time slice (details are in *Materials and Methods*, *SI Text*, and Fig. S7). Hence, all box model runs accepted in this study are consistent with the presented ice core constraints within the error limits of the data.

Here, we focus on the model results for GEM and BB presented in Fig. 2, showing a clear and expected anticorrelation of the emission strengths of the two sources (because both are enriched in ^{13}C and D relative to the microbial source). Moreover, Fig. 2 shows that, for any given GEM value, BB emissions are higher in the Holocene and the LGM compared with previous interglacials and glacial, respectively (*Biome and Fire Regime Changes Caused by Megafauna Extinction*). We can use Fig. 2 to constrain possible GEM, where we can safely assume that GEMs are the same during the Holocene compared with previous interglacials and the same for the LGM compared with previous glacial maxima. Our model results allow individual scenarios with higher GEMs for glacial compared with interglacials (Fig. 2). However, because BB emissions must always be larger than zero, an absolute upper limit of interglacial (glacial) GEM is 90 (70) $\text{Tg CH}_4 \text{ a}^{-1}$ (Terragram methane per year) according to our data constraints. Using independent estimates of Holocene and LGM BB emissions (10, 32, 36, 63–66) of 25 and 15 $\text{Tg CH}_4 \text{ a}^{-1}$, respectively, GEMs are in fact smaller than 47 (Holocene) and 41 (LGM) $\text{Tg CH}_4 \text{ a}^{-1}$. It is important to stress that our mean Holocene estimate is based on krypton-free $\delta^{13}\text{CH}_4$ data, resulting in lower $\delta^{13}\text{CH}_4$ values and thus, slightly lower GEMs compared with previous assessments (63, 64) of the Late Holocene (discussion is in *SI Text*).

Overall, we conclude that GEMs (seeps and marine clathrates) are at no point the dominant contributor to the global methane budget, and they are not strongly variable players that could explain the observed glacial/interglacial $[\text{CH}_4]$ variations over the last few hundreds of thousands of years (Figs. 1 and 2 and *SI Text*) (25, 31–33, 36, 62). Thus, we infer that microbial sources must represent the dominant control for natural atmospheric CH_4 changes.

The Role of High Northern Latitude Microbial Emissions. Recently, Köhler et al. (67) calculated that—dependent on assumptions on the gas age distribution of the bubbles in the ice—up to 14 $\text{Tg CH}_4 \text{ a}^{-1}$ could have been released into the atmosphere from

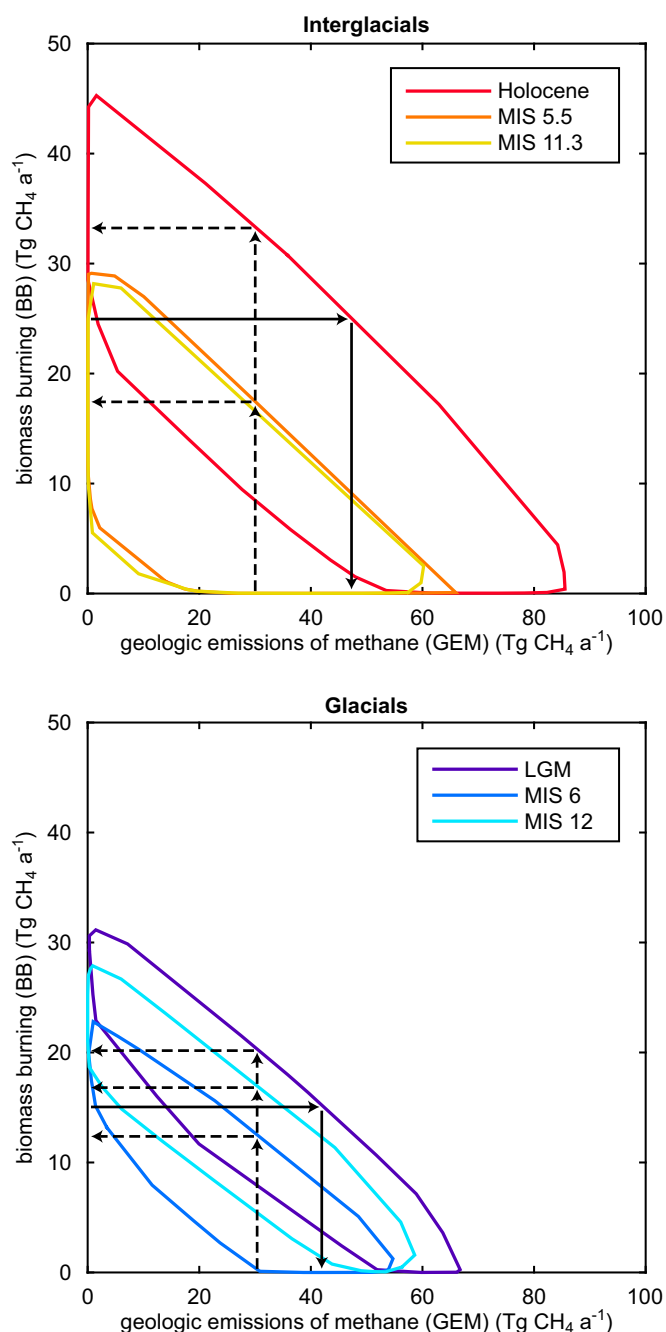

Fig. 2. Box model results fulfilling the ice core constraint. Shown are emission strengths of BB and GEM. Each envelope encloses all 10,000 valid realizations of the Monte Carlo processes searching the parameter spaces of the six time periods (*SI Text* and Table S1). The Matlab function `convhull()` was used to determine the envelope around the solutions for each time slice. *Upper* shows results for interglacials, and *Lower* shows results for glacial. Model results for the Holocene and the LGM are considerably shifted toward higher GEM and/or BB because of the ^{13}C - and D-enriched isotope targets of these younger time slices (Fig. 1 and Table S1). Arrows indicate possible readouts to assess maximal GEM for all investigated time periods (solid lines) and increased BB for the Holocene and the LGM compared with previous time periods (dashed lines).

permafrost thawing (a source relatively depleted in ^{13}C and D) over the Oldest Dryas–Bölling/Alleröd (OD-BA) transition. Unfortunately, the resolution of our $\delta\text{D}(\text{CH}_4)$ data for this event is insufficient to give a direct and qualified answer. For the

Younger Dryas–Preboreal (YD-PB) transition, Melton et al. (68) argued that it is possible to close the isotopic budget by a parallel increase in ^{13}C - and D-enriched emissions from BB and depleted emissions from thermokarst lakes. However, given our information on a gradual and modest decrease of $\delta\text{D}(\text{CH}_4)$ over this transition decoupled from the strong $[\text{CH}_4]$ increase (Fig. S3), this argumentation is only one valid scenario. We argue that a dominant contribution of D-depleted high-latitude emissions (in which we include thawing permafrost/thermokarst lakes/boreal wetland emissions) to the rapid CH_4 increases is unlikely, because the gradual decrease in $\delta\text{D}(\text{CH}_4)$ during the Preboreal starts only after $[\text{CH}_4]$ is already high (Fig. S3). For the Younger Dryas, $\delta\text{D}(\text{CH}_4)$ stays at -62‰ and does not change over the YD-PB transition. Also, there is no imprint of rapidly increasing ^{13}C -depleted emissions from northern high-latitude wetlands (as proposed in ref. 69) in the rather smooth evolution of $\delta^{13}\text{CH}_4$. For both rapid $[\text{CH}_4]$ rises (OD-BA and YD-PB), explanations are preferred that invoke increasing emissions of sources with small isotopic leverage on $\delta\text{D}(\text{CH}_4)$ and $\delta^{13}\text{CH}_4$ as the main drivers. This kind of emission change is fulfilled by strengthening low-latitude microbial sources, such as predominately C_4 -fed tropical wetlands, which incorporate increasingly depleted water (as seen in $\delta^{18}\text{O}$ records) during methanogenesis at that time (12, 35, 70).

For the Holocene, several authors have suggested higher CH_4 emissions from high-latitude ecosystems relative to the LGM (71–73). Based on pollen analyses, Yu et al. (73) proposed a protopeatland phase as the precursor for the succession from wetlands to fens and later bogs. Because peatlands evolve from fens to bogs, this succession is accompanied by decreasing CH_4 emissions and a shift to lower $\delta^{13}\text{CH}_4$ signatures. The latter may be linked to trophic status, degree of methanotrophy, plant types, or type and quality of organic substrates (49, 74–76). However, because there is a strong reduction of methane emissions during this succession, the source signature effect does not leave a sizable imprint in the CH_4 isotopic signature of the atmosphere. Accordingly, the observed leveling out of $\delta^{13}\text{CH}_4$ changes during the Holocene is in line with decreasing emissions from northern peatlands (49). To close the budget, the increase in $[\text{CH}_4]$ over the latest 4.5 ka calls for an additional source. Several theories have been put forward (42, 72, 77, 78), on which we comment below.

Control of (Sub-)Tropical Wetland and Floodplain Emissions on Atmospheric CH_4 . Multiple lines of evidence suggest that (sub-)tropical (sporadically/seasonally inundated) floodplains, wetlands, and peatlands dominate global natural methane emissions (2, 4, 9–12, 14, 17, 25, 79–87). Our data provide additional support for this hypothesis. To underscore the tropical (Ax) or wet and warm temperate (Cax) climatic boundary conditions (where x denotes any of the second characters of the classical Köppen–Geiger climate classification in table 1 of ref. 88, necessary for such wetlands), we refer to this group of methane-emitting systems as AxCax wetlands throughout. The AxCax wetlands are largely located in regions influenced by seasonal swings of the ITCZ (17, 89–95). Because the sizes of AxCax regions are not evenly distributed in both hemispheres, a good portion of their emissions (located, for example, in Southeast Asia) also contributes to the IPD in methane mixing ratio over a wide range of climate states (9).

Temperature, precipitation, the water table, and net primary production (NPP) are regarded to be the main factors controlling CH_4 fluxes in AxCax wetlands (80, 92, 96, 97). Low $[\text{CO}_2]$ during glacial reduces NPP (98), and we expect decreased fluxes from AxCax wetlands as a direct consequence. However, lower glacial sea level led to newly exposed AxCax landmasses (such as the Sunda Shelf), where wetlands could develop (16). On top of an overall reduction in AxCax CH_4 fluxes during glacial times, substantial ecosystem shifts leading to a larger C_4/C_3 plant ratio may explain parts of the glacial $\delta^{13}\text{CH}_4$ evolution (ref. 25 and references therein).

Specific evidence for the key role of AxCax wetland CH_4 emissions comes from the rather small amplitudes in the $\delta\text{D}(\text{CH}_4)$ response for stadial/interstadial (36) and glacial/interglacial changes (Fig. 1 and Table S1) (31). Because extratropical methane sources have a stronger leverage on the integrated hydrogen isotopic source signature, they are expected to experience larger glacial/interglacial $\delta\text{D}(\text{CH}_4)$ changes than their AxCax counterparts. Records from speleothems (85, 99) and plant waxes (100) located in AxCax climates suggest amplitudes for (meteoric) waters used for methanogenesis that are in line with our atmospheric $\delta\text{D}(\text{CH}_4)$ data (Fig. 1). High-latitude changes in δD of precipitation are much stronger (35, 101) and would lead to $\delta\text{D}(\text{CH}_4)$ changes too large compared with our data if this source were to control the observed CH_4 variations.

The earlier proposal by Ridgwell et al. (102) that flooding of the continental shelves is a main contributor to initial steep methane rises is in line with our dual isotope records.

Apart from the overall glacial/interglacial shifts, the variations in $\delta^{13}\text{CH}_4$ are largely decoupled from the changes in $\delta\text{D}(\text{CH}_4)$. To understand the observed variations in $\delta^{13}\text{CH}_4$ (Fig. 1), we discuss in the following changes on the Indonesian archipelago, a region for which wetland history since the LGM has been studied in great detail and that can, therefore, serve as a blueprint for our process understanding. Recently, Dommoin et al. (103) presented local sea level as the key player controlling Sundaland's wetland extent since the LGM. Rising sea level during the deglaciation and Early Holocene lowers the regional hydraulic gradient, leading to higher water tables for peatlands in this region. Falling local sea levels after 5 ka BP lead to an expansion of peatlands located in the coastal lowlands (103). Furthermore, sea-level changes in the Sunda Shelf region may also control moisture supply in the Indo-Pacific Warm Pool and intensity of monsoonal rainfall (85, 99, 104, 105). Taken together, these findings suggest that AxCax wetland CH_4 emissions from the Indonesian archipelago may vary over precessional timescales because of sea level and precipitation changes. We note that Sundaland represents only a fraction of tropical wetland area, and we suggest that other large-scale tropical methane-emitting systems (like the Amazon and the Congo basins) responded similarly to (local) sea level and hence, hydrological gradient changes. Taken together, wetland methane emissions of South America, Africa, and Sundaland can explain the observed ice core signals.

Dommoin et al. (103) also suggest that the exposure of the Sunda Shelf led to drier conditions after MIS 3, causing degraded inland wetlands during the LGM. We propose that the baseline level of atmospheric methane (2, 106) is in fact determined by AxCax wetlands (located in Sundaland and other AxCax regions) and that its decline to the lowest levels observed in ice cores after MIS 3 is caused by the drying of tropical wetland systems. We observe that the CH_4 response reported for Greenland interstadials (DO 2/3, 18/19/20, and 22/23) during periods of falling sea level is generally small (8, 107, 108). In other words, $[\text{CH}_4]$ only shows large stadial/interstadial increases during periods of rising (local) sea level when insolation and increased monsoon precipitation could, in principle, boost wetland CH_4 emissions (2, 4, 19, 25, 70, 106, 109). Hence, only under the prerequisite of a low(er)ing hydraulic gradient in AxCax wetland regions can any forcing (temperature or precipitation) lead to strong methane production increases during DO events and glacial/interglacial terminations.

One open question remaining is why MIS 5.5 and MIS 11.3 $[\text{CH}_4]$ and $\delta^{13}\text{CH}_4$ histories differ drastically in their temporal evolution, whereas $\delta\text{D}(\text{CH}_4)$ is rather constant: near -89‰ for both interglacials (Fig. 1). Most importantly, a pronounced minimum in $\delta^{13}\text{CH}_4$ is found at the end of MIS 5.5 (116 ka BP) during the time of minimal northern insolation. At the same

time, $[\text{CH}_4]$ decreases continuously toward glacial levels, with a steeper decrease from the minimum $\delta^{13}\text{CH}_4$ values onward. The following scenarios cannot be used to explain the $\delta^{13}\text{CH}_4$ minimum during MIS 5.5. (i) A proportional reduction of all sources. Because this scenario would lead to no signal in $\delta^{13}\text{CH}_4$, it can be ruled out. Thus, a change in the source mix or a shift in the isotopic signature of the (dominant) source(s) is required. (ii) Reduced microbial emissions while keeping geologic and BB emissions constant. Because this combination would produce higher $\delta^{13}\text{CH}_4$ when total CH_4 decreases, it also cannot explain our observations. (iii) Stable or even increasing emissions from microbial, isotopically light sources [such as ^{13}C - and D -depleted (boreal) wetlands and thermokarst, permafrost]. This setting would call for overcompensation by decreasing ^{13}C -enriched emissions to meet falling $[\text{CH}_4]$. Accordingly, decreasing emissions from BB and/or GEM could result in the observed low $\delta^{13}\text{CH}_4$ values. The last two scenarios can be ruled out on the basis of our $\delta\text{D}(\text{CH}_4)$ constraint, because we would expect coevolving trends for both isotopes. In contrast, our $\delta\text{D}(\text{CH}_4)$ data show no clear trend during this time period.

The $\delta^{13}\text{CH}_4$ minimum occurs at the very end of MIS 5.5 at a time when $\delta^{15}\text{N}_2$ and $[\text{CO}_2]$ indicate the end of the warm period (Fig. S3) (50, 51, 110). At that time, $[\text{CH}_4]$ is already close to glacial levels of below 500 ppb (4). We propose that the lowest interglacial CH_4 levels (coincident with northern insolation minima at the start and end of MIS 11.3, the end of MIS 5.5, and the mid Holocene) are also mainly because of decreased AxCax wetland emissions. At the same time, these periods are connected to $\delta^{13}\text{CH}_4$ minima. To close the isotope budget, a simultaneous reduction in a relatively ^{13}C -enriched source is required. Hence, additionally, declining BB emissions are proposed to meet all constraints. Such a scenario is in line with lower BB emissions under cooling climate conditions (24) and recently published speleothem data (70) showing reduced Asian monsoon strength corresponding to low $[\text{CH}_4]$ and low $\delta^{13}\text{CH}_4$ during MIS 11.3 and for the late MIS 5.5 $\delta^{13}\text{CH}_4$ minimum.

Interestingly, CH_4 and $\delta^{13}\text{CH}_4$ decrease during the first one-half of the Holocene but reverse their trend during the second one-half, when northern insolation is still declining. To explain this feature, Ruddiman (77) proposed an early human influence. An alternative scenario meeting all of the constraints presented is that of stronger southern insolation, leading to increasing CH_4 emissions of AxCax wetlands in the tropical Southern Hemisphere (e.g., South America). This scenario is consistent with proxy data (111, 112) and a $\text{CH}_4/\text{climate}$ model study (78). Moreover, our CH_4 and $\delta^{13}\text{CH}_4$ data during MIS 11.3 show the same behavior as in the Holocene. We can conclude that the Holocene trends operate similarly to MIS 11.3, with strong southern insolation causing increased southern tropical AxCax wetland emissions during the last 5 ka. For MIS 5.5, this insolation boost from the south would have come too late and already during falling sea level, causing $[\text{CH}_4]$ to drop continuously.

In summary, we conclude that tropical methane-emitting systems are the key players among all natural methane emitters, reflecting changes in (local) sea level, monsoon strength, and temperature induced by orbital changes.

Biome and Fire Regime Changes Caused by Megafauna Extinction.

Arguably, the most surprising feature of our records (Fig. 1) is the pronounced difference in absolute levels for both $\delta^{13}\text{CH}_4$ and $\delta\text{D}(\text{CH}_4)$ for the Holocene compared with MIS 5.5 and MIS 11.3 and for the LGM compared with MIS 6 and MIS 12. Shifts of $\sim 2\text{--}3\text{‰}$ for $\delta^{13}\text{CH}_4$ and $10\text{--}18\text{‰}$ for $\delta\text{D}(\text{CH}_4)$ toward higher numbers are found, with no obvious difference in CH_4 mixing ratio between these time slices (Table S1) (42). Straightforward explanations for similar $[\text{CH}_4]$ accompanied by shifted isotope records require changes in the source signatures or changes in emission strength of a source with strong leverage. To our knowledge, no

general isotope shifts of that size have been described in precursor materials for methanogenesis before MIS 2. It is also unlikely that the source strength or signature of GEM or biogenic emissions changed markedly compared with previous glacial/interglacial cycles. In fact, GEM is expected to change in response to sea level or ice sheet extent, but the two parameters remain within a similar range for all glacials and all interstadials considered in this study. One possibility to reconcile the observations is CH_4 emission changes related to changes in biomes and fire regimes, because BB is a CH_4 source strongly enriched in ^{13}C and D (13, 22, 65). BB is an ancient and persistent feature throughout the geologic record (113), and there is evidence of net changes in fire regimes as a consequence of the megafauna extinction that was presumably caused by rapid climate changes in combination with human interference in the course of the last glacial (refs. 114–119 and references therein). The review by Johnson (120) on the timing of the arrival of humans on different continents and the ecological consequences of megafauna extinction supports the idea that increased fire frequency was caused by increased vegetation density and the accumulation of plant material not consumed by herbivores. For example, records from Australia of charcoal, different plant pollen types, and spores of the fungus *Sporormiella* are used by Rule et al. (121) to indicate large herbivore activity and conclude that megafauna extinction caused increased fire activity after 41 ka BP. Furthermore, these Australian records show that fires were common during the Holocene but much less frequent in the previous interglacial. We note that responses might be different in other parts of the globe (122–124) and that, today, Australia accounts for only roughly 6% of global fire carbon emissions (125). However, other authors reported similar observations of fire activity changes on other continents (126, 127), but a global synthesis is not available yet.

Assuming similar GEM for all of the time periods investigated, we can derive the net change in BB emissions for different time periods from Fig. 2, where we compare model interglacial (glacial) runs with the same interglacial (glacial) model parameters (all identical except for a small shift from the microbial source to BB). For example, an assumption of 30 Tg $\text{CH}_4 \text{ a}^{-1}$ of GEM results in a shift in BB emissions for the Holocene by 15 Tg $\text{CH}_4 \text{ a}^{-1}$ (or +83%) compared with MIS 5.5 and MIS 11.3. For the LGM, the model results show an increase in BB emissions by about 7 Tg $\text{CH}_4 \text{ a}^{-1}$ (or +54%) compared with MIS 6 and 3 Tg $\text{CH}_4 \text{ a}^{-1}$ (or +18%) compared with MIS 12. Hence, our dual stable isotope records (Fig. 1) directly support the hypothesis (120, 121) of higher fire activity during the Holocene and the LGM compared with previous interglacials and glacials, respectively. At the same time, the largely unchanged CH_4 levels suggest that direct CH_4 emissions from large animals are confined to the lower end of values found in the literature (128).

Conclusions

Stable isotopic methane records from polar ice cores offer insights into past methane emission inventories and significantly improve our quantitative understanding of past atmospheric methane changes. With our dual isotope data, we can rule out a dominant role for GEM in the glacial methane budget and especially, past emission changes. In fact, methane emissions from tropical wetland and seasonally inundated floodplain systems seem to be the strongest source for not only interglacials but also, glacials. These emissions play the major role in the waxing and waning of atmospheric methane mixing ratios recorded in polar ice. Key parameters to control CH_4 emissions in these wetland systems (AxCax wetlands) are temperature and the water table as steered by a combination of solar insolation, (local) sea level, and monsoon strength. Between 80 and 25 ka BP, the CH_4 emissions experienced a shift in both stable isotopes, leading to higher (heavier) values for the younger part. This observation is hard to explain by climate-driven wetland changes. We propose that this shift is caused by biome changes that foster

BB emissions in the course of the late Quaternary megafauna extinction.

Materials and Methods

$\delta^{13}\text{C}_4$ Analysis of Ice Core Samples. All presented $\delta^{13}\text{C}_4$ data were measured at the University of Bern using the system described in detail in ref. 47. All data are free of a krypton interference (48). Blank ice measurements indicate no artifacts associated with ice processing (47). The external precision (1-sigma SD) is estimated based on the long-term repeatability of replicate ice core analyses to be better than 0.15‰ (47). Our reference is a bottle of Pacific air calibrated at the Stable Isotope Laboratory of the Institute of Arctic and Alpine Research (University of Colorado) (47). All $\delta^{13}\text{C}_4$ data are given using the δ notation on the VPDB scale. $\delta^{13}\text{C}_4$ data have been corrected for gravitational settling in the firn using published $\delta^{15}\text{N}_2$ records (*SI Text*). In polar firn, diffusive isotopic fractionation takes place when large and rapid changes of the CH_4 mixing ratio (129, 130) occur. We calculated the expected influence of this effect according to the procedure presented in ref. 129 and apply this correction to the data plotted in our figures. Note that these effects are rather short-lived and very small for our selected samples and do not affect any of our conclusions. $[\text{CH}_4]$ data shown in our figures were obtained using the isotope analysis and have an estimated 1-sigma error of 5 ppb based on TALDICE replicate measurements (47).

$\delta\text{D}(\text{CH}_4)$ Analysis of Ice Core Samples. All presented $\delta\text{D}(\text{CH}_4)$ data have been measured at the University of Bern using the system described in detail in ref. 46. All data are free of a krypton interference. Blank ice measurements indicate no artifacts associated with ice processing (131). For $\delta\text{D}(\text{CH}_4)$, the external precision (used as error bars in the figures) is estimated based on the 1-sigma SD of our daily standard gas measurements used to calibrate the sample. This uncertainty ranged between 0.9‰ and 3.8‰, with a median of 2.1‰. Replicate analyses of ice core samples indicate a reproducibility of better than 2.3‰ (pooled 1-sigma SD for measurements performed during a time period of 3.5 y) (46). All data are given in the commonly used δ notation on the VSMOW scale. Note that no international reference standard for $\delta\text{D}(\text{CH}_4)$ in air/ice core samples exists so far. Our data are tied to the scale of the Institute for Environmental Physics in Heidelberg, Germany using a cross-calibrated bottle of recent air (46). A laboratory offset to measurements from the United States is evident (46). $\delta\text{D}(\text{CH}_4)$ data have been corrected for gravitational settling in the firn using published $\delta^{15}\text{N}_2$ records (*SI Text*). No corrections concerning diffusive isotopic fractionation (129, 130) have been performed for $\delta\text{D}(\text{CH}_4)$ data (*SI Text*), because the size of this correction is negligible compared with the $\delta\text{D}(\text{CH}_4)$ variations.

Box Model. We used the box model presented in refs. 32 and 36 to assess maximal GEM and increased emissions by BB for the last 25 ka compared with previous time periods. The atmosphere of the model consists of four

boxes (northern and southern troposphere and stratosphere) with prescribed air mass exchange. CH_4 emissions into the tropospheric boxes as well as their source signatures and sink fractions are varied in a Monte Carlo approach. The model is run into steady state, and the equilibrium value of the southern troposphere box is compared with the data constraints (Table S1). If the modeled $[\text{CH}_4]$, $\delta^{13}\text{C}_4$, and $\delta\text{D}(\text{CH}_4)$ values are compatible [within the uncertainty of the measured data (Table S1)], the input values are recorded as a possible CH_4 budget solution. For each time slice, 10,000 valid runs are collected. To be consistent with work on the recent methane budget (63), we distinguish only three source categories here: GEM, BB, and a microbial source including natural emissions by wetlands, ruminants, and termites. Isotopic signatures of the sources are based partly on our previous work (refs. 32 and 36 and references therein) and mainly on the collection by Schwietzke et al. (63) with some modifications (details are in *SI Text* and Table S2). In particular, we adjusted the geographical distribution of the sources to be consistent with IPD estimates for $[\text{CH}_4]$ (9, 79, 89, 132) and lowered the isotopic signature of the Northern Hemisphere microbial source. To account for biome shifts during the glacial, we shift the microbial and BB source signatures by +2.6‰ in line with the interpretation given in ref. 25. The model uses four sinks (tropospheric OH, stratospheric loss, soils, and tropospheric Cl), with fractions that have been varied according to Table S3. Overall, our atmospheric isotope constraints are free of a methodologically caused krypton artifact perturbing previous studies, leading to generally lower $\delta^{13}\text{C}_4$ constraints and hence, lower GEM/BB estimates in our study.

ACKNOWLEDGMENTS. We thank Sepp Kipfstuhl and the Alfred Wegener Institute (AWI) for providing EDML samples from MIS 5.5. We also thank Gregory Teste (IGE) for help in sample cutting. Anne-Laure Daniau, Jennifer Marlon, and Cathy Whitlock are acknowledged for helpful inputs on fire histories. We thank two reviewers for their valuable comments. Primary logistical support was provided by Programma Nazionale di Ricerche in Antartide (PNRA) at Talos Dome. The collaborative research on the Vostok ice core was carried out in the frame of the Russian–French International Associated Laboratory Climate and Environments from Ice Archives. The research leading to these results has received funding from the European Research Council (ERC) under the European Union's Seventh Framework Programme FP7/2007–2013 ERC Grant 226172 [ERC Advanced Grant Modern Approaches to Temperature Reconstructions in Polar Ice Cores (MATRICS)] and the Swiss National Science Foundation. This work is a contribution to EPICA, a joint European Science Foundation/European Commission scientific program funded by the European Union and national contributions from Belgium, Denmark, France, Germany, Italy, The Netherlands, Norway, Sweden, Switzerland, and the United Kingdom. The main logistic support was provided by Institut Polaire Français Paul-Emile Victor (IPEV) and PNRA (at Dome C) and AWI (at EDML). TALDICE, a joint European program, is funded by national contributions from Italy, France, Germany, Switzerland, and the United Kingdom. This work is EPICA publication no. 306 and TALDICE publication no. 45.
